Preface

The International Conference on Educational Data Mining (EDM) is the annual flagship conference of the International Educational Data Mining Society. The 19th iteration of the conference, EDM 2026, is participating in the Festival of Learning 2026 in Seoul, Republic of Korea, from June 27 to July 3, 2026. This year's theme is Educational Data Mining Across Borders: Bridging Disciplines, Contexts, and Perspectives. Educational Data Mining has reached a stage where methods and findings are relevant across multiple areas of research and practice. Many of the challenges in learning and teaching cannot be addressed from a single perspective, and solutions are strengthened by crossing disciplinary, contextual, and cultural boundaries. This year's theme highlights work that integrates perspectives, links research and practice, and broadens the impact of educational data mining to support diverse and inclusive learning opportunities.

The scientific programming for EDM 2026 includes:

- Keynote talks by outstanding researchers in the field as part of the Festival of Learning 2026, including EDM's keynote speaker Bongshin Lee (Yonsei University, Republic of Korea).
- A plenary *Prof. Ram Kumar Educational Data Mining Test of Time Award* talk by Radek Pelánek (Masaryk University, Czech Republic), along with a discussion panel.
- A *Data Set Award* talk by Dorottya Demszky (Stanford University, USA) and Heather Hill (Harvard University, USA).
- Tutorials and workshops as part of the Festival of Learning 2026.
- Nineteen paper presentation sessions with 1 or 2 parallel tracks.
- A poster presentation session.
- An industry track session.
- A doctoral student consortium.

This year, EDM received 138 submissions to the Full Papers track (10 pages), 114 to the Short Papers track (6 pages), and 102 to the Posters and Demos track (4 pages). The program committee accepted 32 full papers (23.2% acceptance rate), 24 short papers (21.1% acceptance rate), and 46 poster and demo papers (45.1% acceptance rate). The EDM 2026 Industry track fostered exchange between industry application research and basic research, and 3 papers were included in the industry track. Furthermore, EDM 2026 also continued its tradition of providing opportunities for young researchers to present their work and receive feedback from their peers and senior researchers. The Doctoral Consortium this year featured 19 participants.

We thank all the authors who submitted their work and the program committee members for their expert inputs. We thank the members of the organization committee for their leadership that made this conference possible. We thank the sponsors of EDM 2026 and the Festival of Learning 2026

for their generous support. And, a big thank you to the local organizing committee of the Festival of Learning 2026 who made this event memorable.

Anthony Botelho	University of Florida, USA	Program Chair
Maria Mercedes T. Rodrigo	Ateneo de Manila University, Philippines	Program Chair
Adish Singla	MPI-SWS, Germany	Program Chair
Hiroaki Ogata	Kyoto University, Japan	General Chair
Hyojeong So	Ewha Womans University, Republic of Korea	General Chair
Young Hoan Cho	Seoul National University, Republic of Korea	General Chair

June 27, 2026
Seoul, Republic of Korea

Organizing Committee

General Chairs

- Hiroaki Ogata (Kyoto University, Japan)
- Hyojeong So (Ewha Womans University, Republic of Korea)
- Young Hoan Cho (Seoul National University, Republic of Korea)

Program Chairs

- Anthony Botelho (University of Florida, USA)
- Maria Mercedes T. Rodrigo (Ateneo de Manila University, Philippines)
- Adish Singla (MPI-SWS, Germany)

Equity, Diversity, Inclusion, and Accessibility Chairs

- Anna Rafferty (Carleton College, USA)
- Jade Maï Cock (LIP6 Sorbonne Université, France)

Industry Track Chairs

- Jeeheon Ryu (Chonnam National University, Republic of Korea)
- Hae-Deok Song (Chung Ang University, Republic of Korea)
- Jeongyun Han (University of Seoul, Republic of Korea)

Poster & Demo Track Chairs

- Shashi Kant Shankar (Ahmedabad University, India)
- Irena Koprinska (The University of Sydney, Australia)

Doctoral Consortium Chairs

- Jaclyn Ocumpaugh (University of Houston, USA)
- Nathaniel Blanchard (Colorado State University, USA)

JEDM Track Chairs

- Guanliang Chen (Monash University, Australia)
- Carrie Demmans Epp (University of Alberta, Canada)

Workshop & Tutorials Chairs

- Jina Kang (University of Illinois Urbana-Champaign, USA)
- Benjamin Paaßen (Bielefeld University, Germany)

Awards Chairs

- Tanja Käser (EPFL, Switzerland)
- Nigel Bosch (University of Illinois Urbana-Champaign, USA)
- Mingyu Feng (WestEd, USA)

Web Chairs

- Paul Salvador Inventado (California State University Fullerton, USA)
- Hongming (Chip) Li, Student Volunteer (University of Florida, USA)

Proceedings Chairs

- Miguel Portaz (UNED, Spain)
- Ana Serrano Mamolar (University of Burgos, Spain)

IEDMS Officers

Luc Paquette	President	University of Illinois Urbana-Champaign, USA
Anna Rafferty	Treasurer	Carleton College, USA

IEDMS Board of Directors

Rakesh Agrawal	Data Insights Laboratories, USA
Tiffany Barnes	North Carolina State University, USA
Nigel Bosch	University of Illinois Urbana-Champaign, USA
Neil Heffernan	Worcester Polytechnic Institute, USA
Sharon Hsiao	Santa Clara University, USA
Tanja Käser	EPFL, Switzerland
Kenneth Koedinger	Carnegie Mellon University, USA
Ramkumar Rajendran	Indian Institute of Technology Bombay, India

Program Committee

Senior Program Committee Members

Jill-Jênn Vie	Inria Lille
Anna Rafferty	Carleton College
Sébastien Lallé	Sorbonne University
Roger Nkambou	Université du Québec à Montréal
Sidney D'Mello	University of Colorado Boulder
Andrew Lan	University of Massachusetts Amherst
Tiffany Barnes	North Carolina State University
Mingyu Feng	WestEd
Benjamin Paaßen	Bielefeld University
Jaclyn Ocumpaugh	University of Houston
Irena Koprinska	The University of Sydney
Ashish Gurung	Carnegie Mellon University
Yang Shi	Utah State University
Neil Heffernan	Worcester Polytechnic Institute
Paul Inventado	California State University Fullerton
Sherry Sahebi	University at Albany - SUNY
Ranilson Paiva	Universidade Federal de Alagoas
Collin Lynch	North Carolina State University
Bita Akram	North Carolina State University
Thomas Price	North Carolina State University
Yo Ehara	Tokyo Gakugei University
Agathe Merceron	Berliner Hochschule für Technik
Dragan Gasevic	Monash University
Cristina Conati	UBC
Tanja Käser	EPFL
Atsushi Shimada	Kyushu University

Enkelejda Kasneci	Technical University of Munich
Agoritsa Polyzou	Florida International University
Niels Seidel	FernUniversität in Hagen
Srecko Joksimovic	Education Future, University of South Australia
Ryan Baker	University of Pennsylvania
Caitlin Mills	University of Minnesota
Kirsty Kitto	University of Bergen, Norway
Tiffany Tang	Wenzhou-Kean University
Michel Desmarais	Ecole Polytechnique de Montreal
Carol Forsyth	Educational Testing Service
James Lester	North Carolina State University
Fabiano Dorça	Universidade Federal de Uberlandia
Stephen Fancsali	Carnegie Learning, Inc.
Alexandra I. Cristea	Durham University
Stephan Weibelzahl	Private University of Applied Sciences Göttingen
Johan Jeuring	Utrecht University
Maomi Ueno	The University of Electro-Communications
Jeonghyun Lee	Georgia Institute of Technology
Mirko Marras	University of Cagliari
Nigel Bosch	University of Illinois Urbana-Champaign
Radek Pelánek	Masaryk University Brno
Giora Alexandron	Weizmann Institute of Science
Ramkumar Rajendran	IIT Bombay
Niels Pinkwart	Humboldt-Universität zu Berlin
Roger Azevedo	University of Central Florida
Alex Bowers	Columbia University
François Bouchet	Sorbonne Université - LIP6
Cristobal Romero	University of Cordoba
Jesus G. Boticario	UNED
Zach Pardos	University of California, Berkeley
Sebastián Ventura	University of Cordoba
Ratnavel Rajalakshmi	VIT University, Chennai Campus

Regular Program Committee Members

Rahul Yedida	LexisNexis
Christine Lourrine Tablatin	Pangasinan State University - Urdaneta City Campus
Eric Qiu	Cornell University
Namrata Srivastava	Vanderbilt University
Andres Felipe Zambrano	University of Pennsylvania
Ali Keramati	University of California, Irvine
Ben Khalifa Ghada	PRINCE, Research Lab , ISITCOM
Jacob Whitehill	Worcester Polytechnic Institute
Conrad Borchers	Carnegie Mellon University
Min Zhuang	Phd Student at NCSU
Maria de Los Angeles Constantino González	Tecnológico de Monterrey Campus Laguna
Yiqiu Zhou	University of Illinois at Urbana-Champaign
Daniela Rotelli	Sorbonne Université
Rosalyn Shin	University of Maryland, College Park
Danielle R Thomas	Carnegie Mellon University
Ricky Gole	Morgan State University
Fan Zhang	University of Florida
Briane Paul Samson	De La Salle University
Ivica Boticki	FER UNIZG
Teresa Ober	Educational Testing Service
Aditya Rajbongshi	University of Frontier Technology

JEDM Talks . . . 3

Full Papers

A Causal Framework for Estimating Heterogeneous Effects of On-Demand Tutoring . . . 6
Kirk Vanacore, Danielle R Thomas, Digory Smith, Bibi Groot, Justin Reich and Rene Kizilcec

A New Domain-Informed Learner Model with Uncertainty-Aware Knowledge Mastery Propagation . . . 18
Rania Ait Chabane, Armelle Brun and Azim Roussanaly

A Psychometric Framework for Context-Conditional Evaluation of LLM Tutoring in Programming Education . . . 29
Jinnie Shin, Zhe Li, Pauline Aguinalde and Laura Cruz Castro

CantoTalk: Probing Teacher Expertise From Fine-Tuned Talk Move Representations . . . 44
Mayank Sharma, Xinman Liu and Gordon Yeung

Characterizing Students' LLM Usage Behaviors and Their Association with Learning in Critical Thinking Tasks . . . 57
Minju Park, Ivan Orozco Vasquez and Cristina Conati

Confusion-Aware Rubric Optimization for LLM-based Automated Grading . . . 67
Yucheng Chu, Hang Li, Kaiqi Yang, Yasemin Copur-Gencturk, Joseph Krajcik, Namsoo Shin and Jiliang Tang

Do interviews change participants' behaviors?: Using log data to investigate student reactivity during data-driven classroom interview . . . 79
Hyeongjo Kim, Luc Paquette, Yiqiu Zhou, Qianhui Liu, Jaclyn Ocumpaugh, Andres Felipe Zambrano and Amanda Barany

Engagement-Driven Differences in Acoustic Features During Online Reading Comprehension Conversations . . . 90
E. Margaret Perkoff, Megan Lyons, Alexandria Mulqueen, Ryan S. Baker, Alan Gee, Jaclyn Ocumpaugh, Adam Porsch, Neville Ryant, Julia Parish-Morris and Lyle Ungar

Exploring Temporal Dynamics Underlying Eye Gaze, EEG, and Text Characteristics during Naturalistic Reading with Multi-Level Vector Autoregression 104
Megan Caruso, Robert Moulder, Rosy Southwell and Sidney D'Mello

From Heuristics to Analytics: Forecasting Effort and Progress in Online Learning 117
Eric S. Qiu, Danielle R Thomas, Boyuan Guo, Vincent Aleven and Conrad Borchers

Improving Hybrid Human-AI Tutoring by Differentiating Human Tutor Roles Based on Student Needs 130
Ashish Gurung, Ge Gao, Boyuan Guo, Alex Houk, Erin Gatz, Danielle R Thomas, Shivang Gupta, Lee Branstetter, Emma Brunskill, Vincent Aleven, Kenneth Koedinger and Jordan Gutterman

LLM Reasoning Predicts When Models Are Right: Evidence from Coding Classroom Discourse 143
Bakhtawar Ahtisham, Kirk Vanacore, Zhuqian Zhou, Jinsook Lee and Rene F. Kizilcec

Leveraging Privileged Multimodal Data to Model Cognitive States in an Interactive Learning Platform 155
Deniz Sonmez Unal, Theresa Mowad, Catherine Arrington, Erin Solovey and Erin Walker

MTBU-Bench: a Multimodal Benchmark for Evaluating Video-LLMs in Teacher Behavior Understanding 167
Zhiyi Duan, Jiangshan Guan, Lei Gao and Qianli Xing

Measuring Math or Mouse Skills? Behavioral Dimensions and Multiple Pathways to Test-Taking Efficiency in Computer-Based Testing 180
Xinman Liu and Eunjung Myoung

Multi-dimensional Trajectories of Expertise in Engineering: Perspective from Epistemic Frame Theory 193
Amit Paikrao, Vishwas Badhe, Indrayani Nishane, Jyoti Shaha, Ramkumar Rajendran and Ritayan Mitra

No Single Metric Tells the Whole Story: Interpreting Multiple Pattern Mining Metrics . . . 205
Andres Felipe Zambrano, Jaclyn Ocumpaugh, Ryan S. Baker, Zhanlan Wei, Xiner Liu, Hyeongjo Kim, Qianhui Liu, Jeffrey Ginger, Luc Paquette and Amanda Barany

Pattern-based Knowledge Component Extraction from Student Code Using Representation Learning 217
Muntasir Hoq, Griffin Pitts, Tirth Bhatt, Aum Pandya, Andrew Lan, Peter Brusilovsky and Bita Akram

Personalization in Educational Data Mining and Learning Analytics: A Systematic Review (2015 - 2025) 229
Sylvio Rüdian

Real Enough to Matter? Implications of Synthetic Data for Reproducible Learning Analytics 243
Elena Tiukhova, Grzegorz Meller, Dimitri Van Landuyt, Tinne De Laet, Bart Baesens and Monique Snoeck

Stability and Contextual Sensitivity of Keystroke Process Features in Longitudinal Student Writing Portfolios 256
Damilola Babalola, Naga Buddarapu, Piotr Mitros, Paul Deane and Collin Lynch

Stable and Privacy-Preserving Synthetic Educational Data with Empirical Marginals: A Copula-Based Approach 267
Gabriel Diaz Ramos, Lorenzo Luzi, Debshila Basu Mallick and Richard Baraniuk

Temperature and Persona Shape LLM Agent Consensus With Minimal Accuracy Gains in Qualitative Coding 280
Conrad Borchers, Bahar Shahrokhian, Francesco Balzan, Elham Tajik, Sreecharan Sankaranarayanan and Sebastian Simon

The Cognitive Cost of Poor Item Design: How Item-Writing Flaws Shape Response Time and Difficulty Across Assessment Domains 293
Steven Moore

The Semantic Gap in Behavioral Embeddings: Why Linear Methods Fail for Educational RAG in Mathematics 306
Ricky Gole and Jamell Dacon

Time as a geometric property of the latent space: An empirical study of Time-and-Order RoPE in Knowledge Tracing 317
Willian Costa, Filipe Dwan Pereira, Gabriel Alves, André Nascimento, Luiz Rodrigues, Mario A. P. Santos, Tyagi M. Lima and Rafael Ferreira Mello

To What Extent Do Keystroke Dynamics Differentiate Correct from Incorrect Problem Solving 329
Oscar Deho, Ryan Baker, Digory Smith and Simon Woodhead

Toward LLM-supported Automated Assessment of Critical Thinking Subskills 340
Marisa Peczuh, Nischal Ashok Kumar, Ryan Baker, Blair Lehman, Danielle Eisenberg, Caitlin Mills, Payu Wittawatolarn, Kushaan Naskar, Keerthi Chebrolu, Sudhip Nashi, Cadence Young, Brayden Liu, Sherry Lachman and Andrew Lan

UNVaMP: Neural Knowledge Tracing with Variational Regularization of Latent Knowledge Dynamics 353
Carson Cook, Ahmed Zerouali, Anthony Schmidt, Reginald Ziedzor, Paul Lin and Luke Eglington

Utility-Preserving De-Identification for Math Tutoring: Investigating Numeric Ambiguity in the MathEd-PII Benchmark Dataset 365
Zhuqian Zhou, Kirk Vanacore, Bakhtawar Ahtisham, Doug Pietrzak, Daryl Hedley, Jorge Dias, Jinsook Lee, Rene Kizilcec, Chris Shaw and Ruth Schäfer

What Changes When the Interlocutor Is an AI? Interactional Fluency and Linguistic Uptake in L2 Spoken Dialogue 376
Russell Scheinberg, Ameeta Agrawal, Tetyana Sydorenko, Kalab Kahsay, Nina Vyatkina and Griet Boone

What Do LIWC Features Capture in Multilingual Classroom Talk? A Systemic Functional Linguistic Analysis 388
Kaycie Barron, Ananya Ganesh, Shamya Karumbaiah and Mariana Castro

Short Papers

A Human-in-the-Loop Pipeline for Multi-Class SRL Classification 400
Andreas Sebastian Kissmehl, Olga Viberg, Olov Engwall and Richard Lee Davis

A Three-GenAI Consensus Model for Deductive Analysis of Response Data 408
Amruth Kumar, Renée McCauley, Bonnie MacKellar and Tammy Vandegrift

An Ensemble Stacking with Perception-aware Meta-learning (ESPM) for Apprenticeship Dropout Prediction in France 415
Duaa Baig, Diana Nurbakova, Sylvie Calabretto and Baba Mbaye

Augmenting Student Profiles and Course Attributes with Large Language Models for Course Recommendation 422
Tianyuan Yang, Ren Baofeng, Chenghao Gu, Feike Xu, Boxuan Ma and Shinichi Konomi

Cross-Context Urgency Detection in MOOC Forums 430
Shreya Singhal

Estimating IRT Parameters from Text via an ICC-Based Supervised and Contrastive Loss . . 437
Yoshiki Hori, Takumi Itamiya, Iwao Tanuma and Emiko Yoshihara

Fair When Sparse, Accurate When Rich: RL-Gated Conversational Fusion for Temporally Equitable Knowledge Tracing 446
Fan Zhang, Rui Guo and Hai Li

Federated Code-Aware Knowledge Tracing for Privacy-Preserving Student Performance Forecasting 453
Anurata Prabha Hridi, Muntasir Hoq, Seyyedali Hosseinalipour, Rajeev Sahay and Bita Akram

From Flat to Structural: Enhancing Automated Short Answer Grading with GraphRAG . . . 462
Yucheng Chu, Haoyu Han, Shen Dong, Hang Li, Kaiqi Yang, Yasemin Copur-Gencturk, Joseph Krajcik, Namsoo Shin and Hui Liu

How Do Analytic Design Choices Shape MLLM-Based Detection of Non-Verbal Behaviors in 360-Degree Classroom Video 469
Yiqiu Zhou, Chris Palaguachi, Jina Kang, Luc Paquette, Noah Schroeder, Zhenhailong Wang and Yuji Zhang

Identifying Items on Which Humans and Chatbots Diverge Using Differential Item Functioning 479
Licol Zeinfeld, Alona Strugatski, Ziva Bar-Dov, Ron Blonder, Shelley Rap and Giora Alexandron

Improved Power in a Reanalysis of an ASSISTments Efficacy Trial by Leveraging Auxiliary Data 487
Adam Sales, Kevin Huang, Mingyu Feng and Johann Gagnon-Bartsch

Improving Speech Recognition of Named Entities in Classroom Speech with LLM Revision and Phonetic-Semantic Context 494
Viet Anh Trinh, Xinlu He and Jacob Whitehill

Mining how curiosity spreads in student-led online discussions 500
Farhan Ali

Empowering People to Learn: Inclusive Human-Data Interaction in an AI-Driven World

Bongshin Lee Yonsei University, Republic of Korea

Data and AI increasingly shape how we make decisions, manage our health, understand the world around us, and learn. From wearable sensors and health trackers to personalized dashboards and AI-powered assistants, data has become deeply embedded in everyday life. Data visualization has long served as a powerful means of understanding data and a compelling medium for data-driven storytelling. In this talk, I introduce Human-Data Interaction (HDI) as an essential bridge between data, meaningful insight, and informed action, reflecting on the evolution of my research from data visualization toward a broader exploration of HDI. I will discuss how HDI can empower people to learn from data through reflection, sensemaking, and action. I will also highlight opportunities to help make these data experiences more accessible and inclusive for people with diverse abilities and needs.

Metrics for Evaluation of Student Models

Radek Pelanek Masaryk University, Czech Republic

This talk is based on the paper "Metrics for Evaluation of Student Models", initially published in Journal of Educational Data Mining (Vol. 7, No 2., 2015). Researchers use many different metrics for evaluation of performance of student models. The aim of this paper is to provide an overview of commonly used metrics, to discuss properties, advantages, and disadvantages of different metrics, to summarize current practice in educational data mining, and to provide guidance for evaluation of student models. In the discussion we mention the relation of metrics to parameter fitting, the impact of student models on student practice (over-practice, under-practice), and point out connections to related work on evaluation of probability forecasters in other domains. We also provide an empirical comparison of metrics. One of the conclusion of the paper is that some commonly used metrics should not be used (MAE) or should be used more critically (AUC).

EDM Data Set Award Talk

NCTE Transcript Data

Dorottya Demszky Stanford University, USA
Heather Hill Harvard University, USA

The NCTE Transcript Data focuses on observations of teachers and students in 4th and 5th grade elementary mathematics classrooms. The anonymized transcripts include significant metadata, such as annotation of discourse moves for each turn, information about teacher background and classroom practices, and demographics. It has been used in a variety of applications, including exploring how features of teacher and teacher-student language promote inquiry and growth mindset as well as evaluating and building generative AI systems.

Seeing Is Solving: MLLMs, Reasoning, and Refusal in Visual Math

Ethan Croteau Worcester Polytechnic Institute
Neil Heffernan Worcester Polytechnic Institute

Many middle-school math problems are image-dependent: the diagram or graph carries essential information. This matters for intelligent tutoring and accessibility, where systems must reason over figures and also decline responsibly when figures are missing. We evaluate six contemporary multimodal large language models (MLLMs)—three reasoning models and three non-reasoning models—on 376 Illustrative Mathematics (IM) items labeled as image-role Required (the figure contains task-critical information not recoverable from text alone without added assumptions). Each model attempts every item three times with and without the figure under a shared prompt and scoring protocol. To reduce image-role label subjectivity, we classify items as not Required when they are solvable from text alone without additional assumptions. With images, the top-performing reasoning models achieve accuracy in the mid-50%, while non-reasoning models fall in the mid-30s to low-40s. Without images, models overwhelmingly refuse rather than guess, with only rare correct-by-chance answers. Models show moderate agreement on which items are solvable, and we release two benchmark subsets of items solved consistently across models. A qualitative audit of 83 items shows that visual misreading is the dominant failure mode for non-reasoning models, while reasoning models more often produce correct answers accompanied by adequate explanations. These results suggest tutoring systems should gate automated scoring and learner-model updates on visual-evidence availability and use scaffolds that require explicit visual-evidence binding before algebra. For accessibility, systems should treat no-image refusals as missing-context signals and elicit the figure or a structured description, enabling description-substitution experiments. We release code, prompts, and summary artifacts for replication. Code and data: https://osf.io/ct7bg/.

Using Bayesian Knowledge Tracing to Evaluate Perceptual Scaffolding and Desirable Difficulties in a Math Intervention

PUYUAN Zhang Worcester Polytechnic Institute
Siddhartha Pradhan Worcester Polytechnic Institute
Morgan Lee Worcester Polytechnic Institute
Yanping Pei Worcester Polytechnic Institute
Adam Sales Worcester Polytechnic Institute
Erin Ottmar Worcester Polytechnic Institute

The present study examines the assistance dilemma of providing combinations of perceptual supports in math education by fitting a Bayesian knowledge tracing model (BKT) to an open-source, online order-of-operations intervention dataset. This online intervention dataset contained 688 U.S. middle schoolers' accuracy data who solved order-of-operations problems in pre-test, intervention, post-test, and delayed post-test sessions. Combinations of spacing and color cues were embedded in intervention materials, alongside immediate correctness feedback and worked examples, creating nine between-subject cue conditions (congruent, incongruent, or neutral spacing and/or color). To examine the effect of perceptual cues on immediate performance and long-term learning, we trained a BKT variant, conditioning guess, slip, learn, and forget parameters on perceptual cue conditions. The estimated cue-specific BKT parameters suggest two main findings. First, the presence of congruent perceptual cues (color and/or spacing, e.g., 2 - 8 + 3 x 11) increased guessing rate and reduced slipping rate, suggesting that visually highlighting high-order suboperations facilitated students' immediate problem solving. Second, students who underwent intervention with incongruent color cues (e.g., 2 - 8 + 3 x 11) showed reduced guessing rate but exhibited the highest learning rate and the lowest forgetting rate. These results imply that providing misleading visual highlights may serve as desirable difficulties, which hinder immediate performance but benefit long-term learning. Furthermore, the impact of perceptual cues on immediate performance and long-term learning indicated by BKT parameters approximately aligned with the patterns revealed by behavioral measures (i.e., intervention, post-test, and delayed post-test accuracy). Such consistencies demonstrate the feasibility of using the BKT framework to understand the assistance dilemma of perceptual supports. The code and data are available at this link.

Personalization has become a cornerstone of online learning platforms, offering tailored experiences that enhance learner engagement, satisfaction, and performance. Moving beyond one-size-fits-all approaches, personalized systems can provide flexible access, improved efficiency, and support both cognitive and non-cognitive development. In language learning, personalization affords increased motivation, self-efficacy, confidence, and technology acceptance, while reducing instructor workload. Despite these benefits, many language learning platforms remain non-personalized. This study explores the integration of personalization in an online language learning platform taking into account three learner variables: preference, proficiency, and engagement. Preference captures reported thematic and content choices, proficiency reflects performance-based knowledge levels, and engagement measures sustained interaction or dropout risk. By personalizing based on these learner variables, we aim to tailor learning materials that align with learners' interests, match their abilities, and foster sustained participation. To our knowledge, this is the first study to investigate these three variables collectively in an online language learning platform, contributing to the advancement of personalized technology-enhanced language learning and personalized language learning. Across the three personalization variables, the experiments reveal that lightweight recommender systems outperform deep models for preference prediction, DeepIRT offers the strongest while interpretable proficiency estimates, and random survival forest, especially when informed with proficiency estimates, most effectively models engagement. In the context of NedBox as a use case, and in line with teachers' views on meaningful personalization, these models enable homepage learning material recommendations driven by learner preference and engagement, as well as proficiency-aligned exercise entry points. The source code is provided as a supplementary file for this submission.

A Causal Framework for Estimating Heterogeneous Effects of On-Demand Tutoring

ABSTRACT

This paper introduces a scalable causal inference framework for estimating the immediate, session-level effects of on-demand human tutoring embedded within adaptive learning systems. Because students seek assistance at moments of difficulty, conventional evaluation is confounded by self-selection and time-varying knowledge states. We address these challenges by integrating principled analytic sample construction with Deep Knowledge Tracing (DKT) to estimate latent mastery, followed by doubly robust estimation using Causal Forests. Applying this framework to over 5,000 middle-school mathematics tutoring sessions, we find that requesting human tutoring increases next-problem correctness by approximately 4 percentage points and accuracy on the subsequent skill encountered by approximately 3 percentage points, suggesting that the effects of tutoring have proximal transfer across knowledge components. These effects are robust to various forms of model specification and potential unmeasured confounders. Notably, these effects exhibit significant heterogeneity across sessions and students, with session-level effect estimates ranging from $-20.58pp$ to $+19.95pp$. Our follow-up analyses suggest that typical behavioral indicators, such as student talk time, do not consistently correlate with high-impact sessions. Furthermore, treatment effects are larger for students with lower prior mastery, which was true for both higher and lower socioeconomic status students. This framework offers a rigorous, practical template for the evaluation and continuous improvement of on-demand human tutoring, with direct applications to other forms of on-demand assistance, including emerging AI conversational tutoring interventions.

Keywords

Tutoring, Adaptive Learning Systems, Causal Inference.

1. INTRODUCTION

Kirk Vanacore, Danielle R Thomas, Digory Smith, Bibi Groot, Justin Reich, and Rene Kizilcec. A Causal Framework for Estimating Heterogeneous Effects of On-Demand Tutoring. In Anthony Botelho, Maria Mercedes T. Rodrigo, Adish Singla, Hiroaki Ogata, Hyojeong So, and Young Hoan Cho (eds.) Proceedings of the 19th International Conference on Educational Data Mining, Seoul, Republic of Korea, June, 2026, pp. 6–17. International Educational Data Mining Society (2026).

Tutoring is widely recognized as one of the most effective educational interventions, particularly for students struggling academically [10, 15, 23, 21]. However, recent large-scale evidence suggests that the magnitude of K-12 tutoring effects varies widely across contexts, populations, and implementations, complicating efforts to generalize findings and guide policy decisions [20]. Much prior work has focused on "high-dosage" tutoring, which is typically defined as sustained, scheduled sessions delivered multiple times per week [33]. However, a growing class of interventions provides on-demand tutoring: brief support intended to deliver instruction precisely at moments of student difficulty [9, 22]. These interventions are increasingly embedded within adaptive learning platforms and are delivered by human tutors or AI-based agents [30, 22].

These embedded tutoring systems generate rich, fine-grained interaction data, creating unprecedented opportunities for continuous evaluation and improvement. However, they also introduce a fundamental methodological problem: students self-select into tutoring at moments of struggle, creating severe time-varying confounding that undermines naive observational comparisons. As a result, despite the growth of embedded tutoring systems, the field lacks scalable methods for rigorously estimating the causal impact of individual tutoring interactions in real-world learning platforms.

This paper addresses this gap by introducing a scalable causal inference framework for estimating the effect of on-demand assistance – in this case, human tutoring – within an adaptive mathematics learning platform. Rather than evaluating entire programs or long-term interventions, the framework is designed to estimate the immediate causal effect of individual tutoring sessions on subsequent student performance. Our proposed framework integrates three components into a unified pipeline: (1) principled construction of analytic samples to approximate counterfactual comparisons, (2) latent knowledge state estimation using Deep Knowledge Tracing (DKT; [29]) to address time-varying confounding, and (3) estimation of conditional average treatment effects for local, individual tutoring sessions using Generalized Random Forests (Causal Forests; [3]). In combination, these components provide a practical template for estimating average treatment effects and effect heterogeneity from large-scale learning interaction logs.

We further demonstrate various robustness tests for this framework, showing that with and without contextual variables from outside of the platform (e.g., standardized assessments and demographic variables), this pipeline produced consistent estimates of the tutoring effects. Our framework addresses central challenges in observational studies of educational interventions, including self-selection into treatment, unmeasured baseline ability that changes as students learn, and treatment effect heterogeneity. Furthermore, it provides opportunities to better understand when, for whom, and why tutoring is effective. Finally, this method could be used to estimate outcomes for evaluating AI models for tutoring.

Applying our framework to data from an embedded tutoring system, we find that requesting tutoring has a positive impact on immediate performance by increasing the likelihood that students answer the next problem correctly by an average of 4.01 percentage points (*pp*). We further find that this affects near transfer across skills: tutoring increases the probability of answering the first problem on the subsequent skill correctly by 2.73*pp*. However, there is substantial variability in these effects, with local effect estimates ranging from $-20.58pp$ to $19.95pp$ for immediate performance correctness and from $-23.25pp$ to $+18.24pp$ for near transfer. We find that these estimates are robust to potential confounding from sample selection or unmeasured confounding. However, our marginally nonsignificant placebo suggests that these effect estimates may be biased towards underestimating the effect sizes. Students with lower estimated prior knowledge tended to benefit more from tutoring, although this relationship was slightly attenuated for lower-income students. We conclude by discussing how causal approaches of this kind can help researchers and practitioners better understand and evaluate the mechanisms that drive effective on-demand tutoring, ultimately informing the design of improved human and AI tutoring systems.

2. BACKGROUND

2.1 Efficacy and Heterogeneity in Tutoring Interventions

Tutoring is widely recognized as one of the most effective academic interventions for improving student learning outcomes [10, 15, 23]. Comprehensive meta-analyses have found that tutoring consistently yields significant positive effects on student learning [21, 23]. These effects are impactful across grade levels and subject areas, often outperforming other educational interventions such as class-size reduction or extended school days [15, 23]. However, the efficacy of tutoring is rarely uniform; effects are often heterogeneous across different implementations [23]. Impact also varies significantly according to characteristics such as prior achievement, socioeconomic status, and baseline achievement [10]. Although tutoring often targets lower-performing students to close achievement gaps [15], other studies on voluntary, on-demand models suggest that students with higher baseline engagement or fewer structural barriers are sometimes more likely to access and benefit from support [2, 9]. Understanding this heterogeneity is crucial to determine whether specific tutoring interventions narrow achievement gaps or inadvertently widen them due to differential uptake.

The magnitude of tutoring effects is also inextricably linked to the implementation model. Much of the literature advocates for "high-dosage" tutoring, typically defined as sustained, scheduled sessions occurring three or more times per week, as a primary driver of efficacy [21, 23]. However, scaling such intensive models presents logistical and financial challenges. Consequently, many Adaptive Learning Systems (ALS) have adopted "on-demand" or "just-in-time" models, where brief support is triggered by students making specific errors rather than a fixed schedule [30, 38, 22]. Although scalable, these embedded interactions complicate the traditional definition of dosage, as exposure to treatment becomes a function of student agency and immediate need rather than administrative assignment.

2.2 Integrating Human Tutoring in Adaptive Learning Systems

To address the scalability and cost constraints of high-dosage human tutoring, recent approaches have integrated human support directly into ALS. "Hybrid" or "human-in-the-loop" models aim to combine the personalized, immediate feedback of AI-driven software with the motivational and complex pedagogical support of human tutors [6, 38]. Research suggests that human tutoring can enhance the benefits of ALS [14]. For instance, human tutors—guided by real-time dashboards to intervene when students struggle—yields statistically significant additional boosts in time-on-task and skill proficiency within an ALS, compared to students working in an ALS alone [14]. These hybrid approaches seem to benefit lower-performing students more than higher-performing ones, suggesting that human intervention may most benefit students who most need it [38].

Integrated tutoring models often take the form of "on-demand" chat support embedded within the learning environment. In these settings, the ALS identifies a knowledge gap or a specific misconception, and a human tutor enters the loop to provide targeted scaffolding [17]. Evaluations of such systems have shown that students who engage with this hybrid support demonstrate higher learning gains and knowledge transfer than those using the ALS in isolation [17, 22]. Furthermore, interventions explicitly designed to combine human tutoring with ALS personalization have been shown to nearly double math learning gains compared to control groups, providing a scalable mechanism to promote educational equity for marginalized students [6]. By offloading rote instruction to the ALS and reserving human capital for high-value interactions, these systems offer a promising pathway to deliver effective tutoring at scale [6, 38, 42].

2.3 Methodological Challenges in Estimating On-Demand Effects

Although the efficacy of tutoring is well-documented, estimating the causal impact of on-demand help within adaptive systems presents unique methodological hurdles. Unlike scheduled "high-dosage" tutoring, where attendance is often mandated or fixed, "on-demand" support is driven by student agency. This introduces a specific form of confounding: students are more likely to ask for help precisely when they are least likely to succeed without it [2, 33]. Consequently, naive comparisons between tutored and non-tutored problem attempts often yield negative correlations, reflecting the student's struggle rather than the intervention's failure.

To address this, prior EDM research has largely relied on two approaches: experiments/randomized controlled trials (RCTs) and observational matching strategies. While RCTs remain the gold standard, they are often implemented at the school or student level to evaluate general program access rather than specific interactions [9, 34, 22]. Randomizing individual help requests, which may require denying help to a struggling student for the sake of experimental control, is often ethically prohibitive and disruptive to the learning experience (e.g., wait-list designs where students are randomly assigned to get help right away or later are still disruptive). As a result, granular, problem-level insights must often be derived from observational data. In observational settings, researchers have traditionally employed propensity score matching to balance treatment and control groups on observed covariates such as prior achievement, demographics, and topic difficulty [6]. However, standard matching approaches typically rely on static or slowly changing variables (e.g., pre-test scores, diagnostic assessments). These measures fail to capture the highly dynamic, time-varying nature of a student's knowledge state during a learning session. A student's decision to ask for help is often a function of immediate confusion or a specific misconception, which static or slowly-changing covariates cannot detect.

More recent work has attempted to incorporate dynamic measures of mastery into causal estimation. Approaches such as the "Rebar" and "ReLOOP" method have demonstrated that using predictions from high-dimensional models as covariates can reinforce matching estimators and reduce bias [36, 25]. These methods allow for more precise effect estimation in the contexts of RCTs but are underutilized in observational studies where conditions are not randomized.

A related significant yet underdeveloped area in Educational Data Mining (EDM) is the integration of knowledge tracing (KT) into observational causal inference frameworks to account for time-varying confounding rooted in a student's historical performance [1, 24, 27]. In particular, DKT extends this by utilizing recurrent neural networks to generate high-dimensional latent states that capture complex temporal dependencies in student learning [29]. However, even with these richer representations, standard regression or linear adjustments may not fully account for the complex, nonlinear heterogeneity in how different students respond to tutoring.

Finally, most causal studies in EDM and related fields focus on average treatment effects [36, 25] or subgroup analyses [18, 19, 28, 30]. A growing body of work also examines heterogeneity by how students interact with learning environments [37, 26, 39, 40]. However, the field would benefit from methods that estimate local, session-level estimates of effectiveness. These estimates could be leveraged to flexibly explore the circumstances under which ALS elements, like on-demand tutoring, are most effective, including elements of heterogeneity based on how students respond.

3. CURRENT STUDY

The current study proposes an observational approach for evaluating tutoring sessions embedded within digital learning platforms by estimating their impact on students' subsequent performance. The approach integrates DKT–based estimates of students' latent knowledge states into a causal inference framework, based on the assumption of strong ignorability, that combines causal forests for counterfactual outcome estimation with augmented inverse probability weighting to obtain doubly robust, session-level treatment effects. Together, these methods yield estimates of individual tutoring session effectiveness and enable downstream analyses that characterize heterogeneity in tutoring impacts across students, contexts, and instructional conditions. We use this framework on data from Eedi, an ALS that focuses on helping students overcome math misconceptions, during which students can access on-demand human tutoring through brief text chats.

4. CONTEXT

4.1 Data

The data used for this analysis came from the treatment arm of a multi-year randomized controlled trial (RCT) designed to estimate the causal impact of Eedi on middle school mathematics achievement. Schools were randomly assigned to treatment or control conditions at the school level, with the treatment group receiving access to Eedi for two full academic years while control schools continued with business-as-usual instruction. Our current sample only includes the treatment arm of this RCT: the 12 schools and 2,585 students who had access to and used Eedi during the two-year study.

The original RCT was conducted by an independent professional evaluation organization that was not involved in the present study. The evaluation organization followed an ethics protocol that included school consent, safeguards to ensure that study procedures did not deviate from typical daily instruction, and legally compliant data handling. All data transferred from Eedi to the researchers were fully deidentified. The current study was also approved by Cornell's institutional review board (IRB0149250).

4.2 Eedi

This study was run in Eedi, which is a digital mathematics platform designed to support middle school students by identifying and addressing misconceptions in real time through diagnostic assessment. Eedi uses a large bank of carefully engineered multiple-choice questions, where each incorrect option maps to a specific, well-documented mathematical misconception. This design allows Eedi to pinpoint gaps in understanding at a fine grain and respond with targeted support, including short video explanations, structured practice, and follow-up diagnostic questions. Teachers can deploy the system flexibly in lessons or as homework, using its analytics dashboards to see patterns of misunderstanding across individuals and classes and to adapt instruction accordingly. Students work independently on quizzes of five questions assigned by their teachers. Based on their answers, Eedi responds adaptively with a sequence of hints, videos, and fluency practice to help students overcome misconceptions. Evidence from a large, school-level randomized controlled trial suggests that the platform can produce modest but meaningful improvements in mathematics attainment when implemented over an academic year [17].

4.3 On-Demand Tutoring in Eedi.

Within Eedi, human tutoring was implemented as on-demand, synchronous, one-to-one chat-based support integrated directly into students' ongoing problem-solving activity. At any point, students could initiate a live session that immediately connected them with an expert tutor. Tutors received structured context at the start of each session—including the problem text, the student's answer, and the associated misconception, allowing them to provide targeted, dialog-based support focused on diagnosing and resolving misunderstandings before students returned to independent work.

The intervention involved seventeen tutors, each with at least three years of teaching experience and specific training in tutoring. Sessions were designed to be brief and task-focused, enabling students to move fluidly between independent practice and individualized help. Tutors communicated exclusively through text chat and used a Socratic approach that emphasized questioning and guided reasoning rather than direct answer-giving. Sessions concluded once students demonstrated sufficient understanding or chose to resume their lesson, positioning tutoring as a scalable, just-in-time complement to the broader Eedi's learning environment.

Table 1 summarizes the characteristics of the tutoring sessions. Tutoring sessions were relatively brief, with a median duration of 4.2 minutes and 14 messages exchanged. Tutors contributed approximately 60% of messages on average, consistent with their role in guiding the dialogue.

Table 1: Tutoring Session Characteristics

Metric	Mean	Median	Q25	Q75
Total Messages	17.7	14	9	23
Tutor Messages	10.5	8	5	14
Student Messages	7.2	6	3	9
Duration (minutes)	5.4	4.2	2.4	6.9

5. METHODS: CAUSAL FRAMEWORK FOR LOCAL EFFECT ESTIMATION

Our causal inference framework consists of three interconnected stages, illustrated in Figure 1. (1) First, we construct an analytic dataset that links each tutoring intervention to its immediate outcome while defining an appropriate control group. (2) Second, we train a DKT model on a held-out sample of students to generate latent representations of student knowledge for both the treatment and control samples. (3) Third, we apply a Causal Forest estimator that jointly estimates propensity scores and treatment effects using the DKT-derived hidden states and predicted probabilities as covariates. We validate our findings through a series of robustness checks that incorporate contextual covariates (e.g., school assignment, standardized assessments, and demographics), alternative sample configurations to address potential participation bias, and a placebo outcome test. This framework addresses three central challenges in observational tutoring research: confounding from baseline knowledge differences, self-selection into treatment, and heterogeneity in treatment effects across students.

5.1 Analytic Sample Construction

Our method requires three samples: treatment, control, and hold-out. Table 2 presents the sample breakdown. When a student received tutoring on a problem, that instance entered the treatment sample. The next problem the student attempted without help served as our *immediate performance* outcome, and the next problem on a new skill served as our *near transfer* outcome. To ensure comparability, only problems for which at least one student received tutoring were included in the causal analysis. In addition, problem attempts from treated students in which they did not receive tutoring were excluded from the primary analysis. Treated observations were also excluded when no subsequent problem attempt was available to serve as an outcome.

Table 2: Analytic Sample Construction from Raw Data to Final Analytic Sample

	Students	Problem Attempts	Unique Problems
Original Usage Data	2,585	852,274	8,540
Treatment Sample			
All Treatment Usage	1,234	465,619	6,803
Excluded	(13)	(460,456)	(5,337)
Final Analytic Treated	1,221	5,163	1,466
Control Sample			
All Control Usage	1,351	386,655	8,017
DKT Training	676	197,332	7,485
Holdout			
Control Analysis	675	189,323	5,884
Excluded	(10)	(97,874)	(4,418)
Final Analytic Control	665	91,449	1,466
Total Analytic Sample	1,886	96,612	1,466

To avoid potential Stable Unit Treatment Value Assumption (SUTVA) violations [35], only students who never received tutoring were eligible for the control sample, as prior exposure to tutoring could influence later outcomes. We relax this restriction in a robustness check to assess whether this sample construction meaningfully affects results (see Section 5.4). Students who were never treated were randomly divided between the control and hold-out samples. The hold-out sample was used exclusively for DKT estimation (Section 5.2), while the control sample was reserved for causal effect estimation. The analytic control sample, therefore, consisted of students who (a) never received tutoring and (b) attempted at least one of the same problems as students in the treatment sample. Because not all problems overlapped with tutoring interventions, control-group attempts on non-overlapping problems were excluded. Students who lacked any problem attempts overlapping with the treatment sample were removed from the final analytic control sample.

5.2 Knowledge State Estimation

We implemented a DKT model using a Long Short-Term Memory (LSTM) architecture to generate student knowledge estimates used as pre-treatment covariates in the causal analysis [29]. The model uses a student's sequential history of question attempts to predict the probability of correctly answering subsequent questions. Critically, the model maintains a latent hidden state that encodes information from prior performance across time, allowing it to summarize a student's evolving knowledge state even when past interactions involve different constructs than the one being predicted.

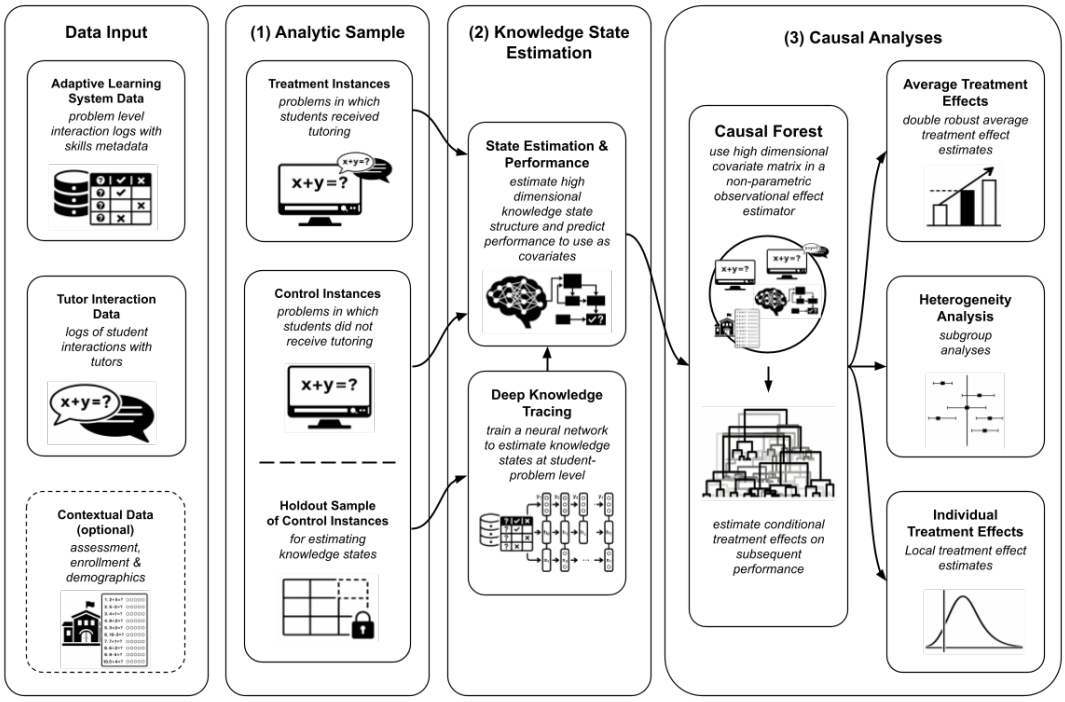

Figure 1: Causal Framework for Estimating Heterogeneous Effects of On-Demand Tutoring. The pipeline integrates ALS and tutor interaction logs to estimate student knowledge states and causal effects. These estimates drive downstream insights into effect variability. While the framework functions independently of contextual data, we incorporate it here to test robustness and identify variables for heterogeneity analysis.

The use of DKT serves a substantive causal purpose. Student knowledge is a key confounder in this setting: students are more likely to seek or be offered tutoring when they are struggling, and baseline knowledge strongly predicts future performance. By conditioning on a rich, multidimensional representation of students' latent knowledge states, we aim to reduce bias arising from time-varying confounding in tutoring assignment and outcome generation. Furthermore, DKT can provide specific point-in-time estimates of baseline knowledge that account for recent learning, which may be more robust than global pretest measures.

We implemented the DKT model in PyTorch following the architecture first introduced by Piech et al. [29]. The training data included 197,332 problem attempts across 7,485 problems representing 1,598 distinct knowledge components. Item embeddings were passed to an LSTM with a hidden dimension of 50, which updated its hidden state h_t at each time step. The resulting 50-dimensional hidden state vector $(H_1, \ldots, H_{50})$ was used as the primary knowledge representation in our causal analysis. The output layer applied a sigmoid activation function to produce probability estimates for the next construct. The model achieved an acceptable AUC of 0.72 on the analytic control sample (which was not used for training), consistent with typical performance reported for DKT models [1].

5.2.1 *Feature Extraction.*

For each observation in the treatment and control samples, we extracted the 50-dimensional LSTM hidden state calculated *just prior to the intervention.* We also included the predicted performance on the current problem, in which the student could receive tutoring support, and the subsequent problem, which serves as an outcome. Including these as covariates in causal analysis is modeled after the *Rebar* method, which has been shown to produce precise, unbiased effect estimates by applying models generated from data outside of the treatment and control sample to those samples [36].

5.3 Causal Forest Estimation

We estimated treatment effects using Generalized Random Forests (GRF) as implemented in the `grf` R package [4]. We chose to incorporate causal forests into the pipeline because of their nonparametric flexibility and their ability to model high-dimensional treatment effect heterogeneity [3].

Furthermore, causal forests offer three other advantages that are particularly relevant in our setting. First, they have been shown to perform well under targeted selection, when treatment assignment depends on predictors of the outcome itself [16, 3]. In the context of on-demand tutoring, students are more likely to seek or receive tutoring precisely when they anticipate poor performance absent intervention, rendering treatment assignment endogenous and outcome-driven. Causal forests are explicitly designed to accommodate this form of selection. Second, a key feature is *honesty*, in which separate subsamples are used for tree construction and treatment effect estimation. This sample-splitting reduces adaptive overfitting and supports valid inference by producing out-of-sample counterfactual predictions analo-

gous to leave-one-out estimation [43]. Third, causal forests directly estimate Conditional Average Treatment Effects (CATEs) as flexible functions of a high-dimensional covariate space. Given the richness of our covariates—including the 50-dimensional DKT hidden state representation—this approach enables estimation of fine-grained, unit-specific conditional effects and supports downstream analyses of treatment effect heterogeneity across students and contexts.

5.3.1 Model Specification.

The covariate matrix X included 50 DKT hidden state dimensions, cumulative historical accuracy, and DKT-based probability estimates of correct responses. The forest was trained with 500 trees, honesty enabled, and hyperparameters selected via cross-validation. We specified students as clusters in the causal forest, implementing cluster-robust estimation such that all observations from a given student are assigned to the same subsample during tree construction. As a result, treatment effect estimates account for within-student dependence, and predictions for each student are generated without using that student's own data.

5.3.2 Estimation Engine: Robinson Decomposition and Propensity Modeling

We estimate heterogeneous treatment effects using Causal Forests, which rely on the Robinson decomposition (also known as a residual-on-residual or orthogonalization strategy). Let Y_i denote the observed outcome for unit i, $Z_i \in \{0, 1\}$ the treatment indicator, and X_i the vector of pre-treatment covariates. For each outcome definition (next-problem correctness and next-skill correctness), the procedure first fits two functions using separate regression forests: the conditional mean outcome model

$$\hat{m}(X) = \mathbb{E}[Y \mid X]$$

and the propensity score model

$$\hat{e}(X) = \mathbb{P}(Z = 1 \mid X).$$

These estimates are then used to construct orthogonalized (residualized) variables:

$$\tilde{Y}_i = Y_i - \hat{m}(X_i), \qquad \tilde{Z}_i = Z_i - \hat{e}(X_i), \tag{1}$$

where $\tilde{Y}_i$ represents the deviation of the observed outcome from its covariate-expected value, and $\tilde{Z}_i$ represents the deviation of the observed treatment assignment from its predicted probability. This transformation removes outcome variation explained by baseline covariates and treatment variation explained by selection on observables, yielding Neyman-orthogonal signals for effect estimation.

The Causal Forest is then trained to model the relationship between $\tilde{Y}_i$ and $\tilde{Z}_i$ as a function of X_i, which isolates the causal signal after adjusting for baseline outcome differences ($\hat{m}$) and treatment selection ($\hat{e}$).

Propensity scores are therefore estimated internally as part of the Causal Forest procedure via a regression forest for $\hat{e}(X)$. Valid estimation requires overlap (positivity), meaning each unit must have a non-negligible probability of both treatment and control conditional on X. In our analytic sample, estimated propensity scores ranged from 0.03 to 0.89, with most observations falling between 0.05 and 0.20. Appendix A.1 presents the full propensity score distribution and associated overlap and robustness diagnostics.

5.3.3 Effect Estimates.

We report three types of effects. The Conditional Average Treatment Effect (CATE) provides unit-level predictions, where $\tau(x)$ represents the difference in expected potential outcomes for an individual with covariates x. Specifically, it captures the contrast between the expected outcome if the student receives tutoring, $Y^{(1)}$, and the expected outcome if the student does not receive tutoring, $Y^{(0)}$:

$$\tau(x) = E[Y^{(1)} - Y^{(0)} | X = x] \tag{2}$$

The Average Treatment Effect (ATE) is the population-level effect, computed using Augmented Inverse Probability Weighting (AIPW) scores:

$$\hat{\tau}^{\text{ATE}} = \frac{1}{n} \sum_{i=1}^{n} \left[\hat{\tau}(X_i) + \frac{Z_i - \hat{e}(X_i)}{\hat{e}(X_i)(1 - \hat{e}(X_i))} \big(Y_i - \hat{m}_{Z_i}(X_i)\big) \right] \tag{3}$$

The Average Treatment Effect on the Treated (ATT) is determined by restricting this calculation to treated units and represents the average effects for those who chose the treatment. The use of AIPW makes the ATE and ATT 'doubly robust,' as they combine the outcome predictions with propensity weighting to correct for bias [12]. Thus, if either the outcome model or the propensity score model is misspecified, the estimates remain consistent and asymptotically unbiased.

5.3.4 Heterogeneity Analysis.

To test for moderators of the treatment effect, we treat the estimated unit-level CATEs ($\hat{\tau}_i$) as the outcome variable in a Linear Mixed Model (MLM):

$$\hat{\tau}_i = \beta_0 + \beta_1 \cdot \text{Moderator} + \mu_s + \epsilon_i \tag{4}$$

where μ_s accounts for student-level clustering. This allows us to determine (via significance testing) which moderators explain the variability in treatment effects. Notably, we do not rely on more standard causal-forest heterogeneity summaries such as best linear projection, because our substantive interest extends to moderators that are not included in the causal forest itself, including variables derived from the tutoring sessions. Instead, we use the estimated CATEs as outcomes in follow-up analyses to examine how these external variables relate to treatment effect variation.

5.4 Robustness and Sensitivity Checks

To assess whether the model is robust to misspecification and potential unobserved confounders, we conducted a series of robustness checks. Our first sets of robustness checks determine whether adding different variables or sample configurations influences the results.

5.4.1 External Variables Added

First, we incorporated additional covariates not derived from platform usage. These included standardized pretest scores of mathematical knowledge (NWEA MAP RIT), which provide an external measure of baseline ability independent of

Table 3: Average treatment effect estimates in percentage points across different model specifications.

Model Specification	ATE (95% CI)	ATT (95% CI)
Primary Specification		
Immediate Performance (Next Problem)	4.01^{***} (2.51, 5.51)	3.98^{***} (2.43, 5.54)
Near Transfer (Next Skill)	2.73^{**} (1.12, 4.35)	2.65^{*} (0.99, 4.31)
Robustness Checks		
External Variables Added (Next Problem)	3.93^{***} (2.49, 5.37)	4.71^{***} (2.92, 6.50)
Washout Sample Included (Next Problem)	2.17^{***} (1.17, 3.16)	2.76^{***} (1.91, 3.61)
Placebo Test (Pre-Intervention)	-1.67 (-3.10, -0.24)	-0.71 (-2.15, 0.74)

Bonferroni-corrected significance: * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

platform performance; a gender indicator with three categories (male, female, or neither); and Pupil Premium Funding (PPF) eligibility, a government designation for students from disadvantaged backgrounds that serves as a proxy for socioeconomic status. We also included school identifiers. The goal of this analysis was to test whether the estimated Average Treatment Effect (ATE) remains stable after adding external covariates, which would suggest that the DKT-based features may adequately capture relevant confounding and that the estimated treatment effect is not driven by unobserved demographic or institutional factors.

5.4.2 Washout Sample Included

The second robustness test evaluates potential selection bias arising from defining the control group as students who have *never* requested tutoring. These students may differ from treated students in ways not fully captured by DKT features or other observed covariates. Although restricting the control group in this way helps prevent SUTVA violations (see Section 5.1), it may introduce confounding if never-treated students are fundamentally different from those who seek tutoring. To examine this possibility, we re-estimate the model using an expanded control group that includes students who previously received tutoring, provided that the prior session did not occur within the previous two skills (i.e., a washout sample). This specification allows us to account for potential carryover effects while reducing selection bias by increasing overlap between treatment and control observations.

5.4.3 Pre-Intervention Placebo Test

Next, we conducted a placebo test using an outcome for which no causal effect is possible: student performance on a problem that occurs *before* the tutoring intervention. Placebo or "negative control" outcomes are widely used in causal inference as a diagnostic tool for detecting residual confounding or model misspecification. If the identification strategy is valid, estimated treatment effects on such outcomes should be null, since they temporally precede treatment and cannot be causally influenced by it [11]. We chose a problem three items before the intervention as our placebo outcome to avoid any interference with the intervention. Finding no significant effect on this pre-treatment outcome would therefore provide additional evidence that the method is not simply capturing baseline differences between students who choose tutoring and those who do not, but is instead identifying a genuine causal effect of tutoring.

5.4.4 Additional Checks

Finally, we employ two additional robustness checks that are common in quasi-experimental analyses. We present these in detail in Appendix A. We tested the sensitivity of our results to propensity score model specification and trimming of the distribution tails to ensure common support [8]. To quantify the robustness of our estimates to unmeasured confounding (i.e., omitted variable bias), we calculate the Robustness Value (RV). The RV represents the minimum strength of association that an unobserved confounder would need to have with both the treatment and the outcome (measured in terms of partial R^2) to reduce the estimated treatment effect to zero. This allows us to benchmark the required strength of an unmeasured confounder against observed covariates like prior mastery or student SES.

6. RESULTS

6.1 Treatment Effect Estimates

Table 3 presents the doubly robust average treatment effect estimates from the Causal Forest analysis, with p-values adjusted for multiple comparisons. We find a statistically significant positive effect of tutoring on immediate performance and near transfer. The estimated average treatment effect (ATE) of tutoring on next problem correctness was 4.01 percentage points (*pp*) (CI = [2.51, 5.51]), $p < 0.001$) and accuracy on the first attempt at a problem on the next skill was 2.73*pp* (CI = [1.12, 4.35]). The effects on the treatment group (ATT) were also significant and similar in magnitude.

6.1.1 Robustness and Sensitivity.

Table 3 presents results from several robustness checks designed to evaluate whether specific modeling choices, such as covariate selection and sample construction, influence the stability of the effect estimates. The inclusion of external demographic covariates yielded a nearly identical ATE of 3.93*pp* ($CI = [2.73, 5.51]$). This stability suggests that our Deep Knowledge Tracing (DKT)-derived features successfully capture the requisite student heterogeneity, rendering additional demographic data redundant for the purposes of confounding control. In the model specification that included the washout sample (the control included students who have been treated in the past, but not within two skills), students within the control group produced a lower but still statistically significant estimate of 2.17*pp* ($CI = [1.17, 6.16]$). The convergence and overlapping confidence intervals across these disparate design assumptions provide robust evidence for a consistent causal effect. These checks were replicated for the near-transfer outcome with similarly significant results.

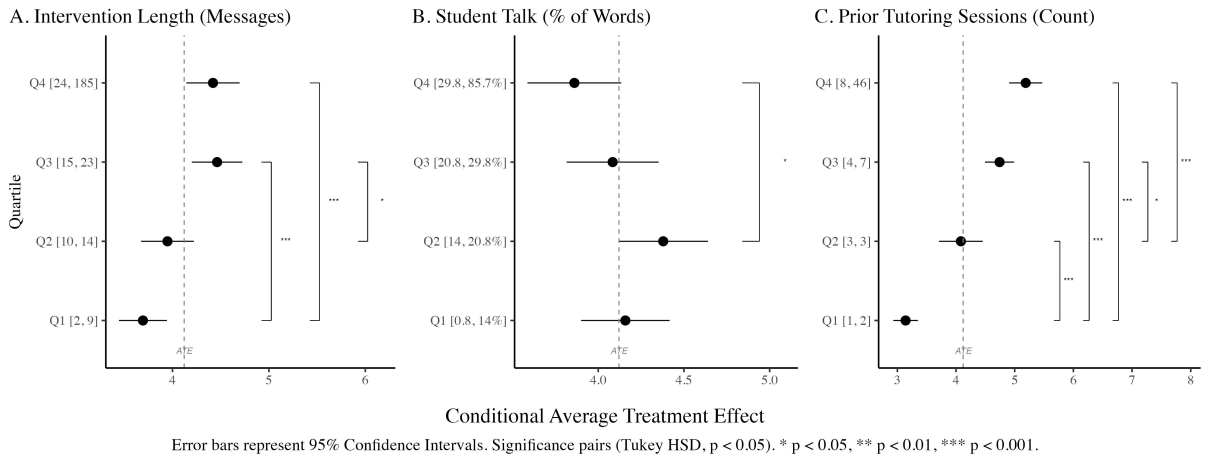

Figure 2: Effect Sizes on Immediate Performance by Tutoring Session Characteristics. Each effect is decomposed by quartiles of the characteristics. Quartile ranges are presented in brackets.

The effect estimate for the placebo outcome—a measure theoretically unaffected by the treatment—was negative and non-significant; however, this is only after applying a Bonferroni correction to account for family-wise error. This result suggests that, if anything, students in the treatment group may actually be biased toward lower baseline performance consistent with targeted selection into treatment; consequently, the observed positive treatment effects are unlikely to be artifacts of model-driven upward bias.

Two additional robustness tests are detailed in Appendix A.1. We utilized paired matching as a diagnostic tool for propensity score estimation, finding that a Random Forest propensity model achieved superior covariate balance compared to linear specifications. Furthermore, we confirmed that trimming the tails of the propensity distribution to ensure stricter overlap did not significantly alter the treatment effect estimates.

Unmeasured Confounding. Finally, as discussed above, the framework depends on a strong ignorability assumption: after conditioning on observed covariates, there are no substantial unmeasured factors that jointly influence tutoring usage and outcomes. This matters here because plausible confounders, such as student motivation, are not directly observed. We assume that some of their influence is expressed through prior performance and interaction histories and is therefore partially captured by the DKT-based covariates, though residual unmeasured confounding may still remain. To test this assumption, we conducted a formal sensitivity analysis [7] by calculating the Robustness Value ($RV_{q=1}$) required to fully explain away the estimated effect.[1] Our results indicate that an unmeasured confounder would need to be at least three times as predictive of both treatment assignment and the outcome as the stroungest predictors (DKT outcome prediction, average accuracy, or cumulative attempts) to nullify the current findings. This level of confounding is unlikely in practice, suggesting the results are robust to plausible omitted variables.

[1]See Appendix A.2

6.2 Treatment Effect Heterogeneity

While the average effects are positive, we observe substantial heterogeneity in local treatment effects across intervention sessions. The CATE for immediate performance has a standard deviation of $3.53pp$, and ranges from $-20.58pp$ to $19.95pp$. The CATE for near transfer has a standard deviation of $3.61pp$, and ranges from $-23.25pp$ to $18.24pp$. Notably, there is a moderate correlation between these effects ($r = 0.46$, $p < 0.001$), suggesting that the immediate performance CATE may be a good, however imperfect, surrogate measure for near transfer; if a tutoring session has a positive effect on next problem correctness, it is likely to have a positive effect on the students' ability to solve problems on other similar skills as well.

6.2.1 *Heterogeneity by Tutoring Session Characteristics*

To illustrate how this method can be used to examine why some tutoring sessions are more effective than others, we analyzed three potential moderators: session length, proportion of student talk, and the number of prior tutoring sessions. We chose these moderators because each of them has been studied in more traditional tutoring environments. Longer and more frequent sessions are consistently pointed to as hallmarks of high-impact tutoring [33]. Eliciting student talk is often associated with higher quality tutoring sessions [5]. Notably, we view this as a preliminary analysis into understanding what might drive effectiveness in on-demand tutoring, which will lead to future directions for this line of work.

Because these variables were non-normally distributed, each was divided into quartiles and compared using the heterogeneity model (Section 5.3.4) with Tukey HSD post-hoc tests.[2] Figure 2 presents the differences in effect size on immediate performance by quartile (quartile descriptive statistics and results tables are presented in Appendix C).

[2]We also ran the models with transformed variables and found similar results, but chose to present the results in terms of quartiles to ease interpretation.

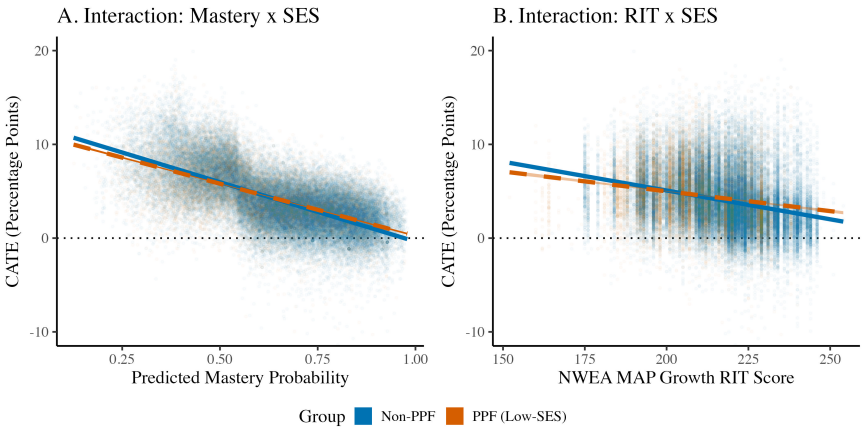

Figure 3: Interactions between prior knowledge in terms of predicted mastery (A) or standardized test scores (B) and socio-economic status (SES) based on Pupil Premium Funding (PPF) eligibility.

Session length was measured by the number of messages sent between the tutors and students that showed the clearest and most consistent pattern. Moderately long sessions (Q3) produced significantly larger effects than shorter sessions (Q1 and Q2; $p < 0.001$), indicating that brief interactions are often insufficient to support learning. Sessions in the longest quartile (Q4) also outperformed the shortest sessions (Q1, $p < 0.05$), but did not yield reliably greater benefits than moderately long sessions, suggesting diminishing returns beyond a certain point.

As a proxy for student talk, we used the percentage of total words in the session that were sent by the student. This measure of the proportion of student talk exhibited minimal and inconsistent associations with tutoring effectiveness. Only one comparison reached significance, indicating slightly lower effects in sessions with the highest levels of student talk (Q4 vs. Q2; $p < 0.05$), with all other contrasts non-significant. Students who sent between 14% and 20% of the words during the session had higher estimated effects than those who sent between 29.8% and 85.7%. This contrasts with much of the work on student talk in tutoring, which often finds that getting students to engage is an important part of tutoring [5]. However, this analysis suggests that student talk may be less important in on-demand sessions that focus on specific problems.

The number of tutoring sessions that preceded the intervention session was strongly and positively associated with impact. Almost all comparisons show that students with more previous sessions experienced substantially larger gains than first-time or infrequent users, with effect sizes increasing monotonically across quartiles. Taken together, these results suggest that tutoring is most effective when sessions are of at least moderate length and when students have prior experience engaging with on-demand support, whereas simply increasing the amount of student talk does not reliably translate into greater effects on proximal performance.

6.2.2 Heterogeneity by Student Characteristics

The CATE estimations also provide opportunities to evaluate which students benefit more from this form of tutoring. To assess this variability, we estimated a series of regression models predicting session-level CATEs (the full table of the model output can be found in Appendix B). Students with lower baseline ability exhibited larger treatment effects, with DKT mastery showing the strongest association ($\beta = -1.87$, $p < 0.001$), indicating that a one standard deviation decrease in predicted mastery corresponded to a 1.87 percentage point increase in effect size. Once DKT was included, NWEA RIT scores showed only a small positive association ($\beta = 0.08$), suggesting that the more proximal DKT-based measure of knowledge was the primary driver of heterogeneity. This pattern is consistent with both a ceiling effect—where higher-performing students have less room to improve—and the hypothesis that just-in-time tutoring is most valuable for students who are struggling.

Overall, low-SES students benefited from tutoring, but to a slightly lesser extent than their peers ($\beta = -0.21$, $p < 0.05$) and interaction terms revealed that the relationship between prior knowledge and treatment effects was weaker for these students (DKT $\times$ PPF: $\beta = 0.14$, $p < 0.001$; RIT $\times$ PPF: $\beta = 0.33$, $p < 0.001$). Figure 3 presents a visualization of this interaction. While lower-performing students generally benefited more from tutoring, this gradient was attenuated among low-SES students. However, as the figure shows, tutoring effects remain strongly related to prior knowledge: on average, lower-performing, low-SES students still appear to benefit more from tutoring than higher-performing, higher-SES students.

7. DISCUSSION & CONCLUSION

This paper introduces a scalable causal framework for estimating problem-level effects of on-demand human tutoring embedded in an adaptive learning system. Across specifications, requesting tutoring produces modest but reliable gains in immediate performance and near transfer.

One central contribution of this work is methodological. We show that time-varying knowledge representations derived from platform logs can be used as pretreatment covariates to address confounding driven by evolving mastery and task difficulty in observational studies of an opt-in feature. By integrating Deep Knowledge Tracing features [29] into a dou-

bly robust causal forest estimator [41, 3, 12], the framework targets the core selection problem that tutoring is typically requested when students anticipate poor performance. The stability of ATE estimates after adding external covariates (test scores, SES proxy, school identifiers) suggests that platform-derived learning traces capture much of the relevant confounding structure. However, the marginally non-significant negative placebo effect may suggest some bias in the approach, but, in this application, that bias is likely an underestimation of the effect.

A key substantive result is that the ATE alone masks wide heterogeneity, including strongly positive and negative session-level effects. Although the average tutoring effect is comparable to lower-cost ALS features such as on-demand hints [13, 32, 31], individual effects range from roughly +20 to −20 percentage points. This indicates that some tutoring sessions are highly effective while others are neutral or counterproductive.

Our analysis of this heterogeneity provides a preliminary, though not comprehensive, attempt to identify the factors associated with higher-impact tutoring. Evaluating session characteristics highlights several potential drivers of effectiveness. Session length exhibits the clearest pattern: moderately long sessions (outperform very short sessions, while the longest sessions do not reliably improve upon moderately long ones. This suggests a diminishing marginal return on tutor time beyond a certain threshold. It is also possible that longer conversations indicated the need for additional remediation beyond what can be provided through a chat interface.

Furthermore, prior intervention experience is strongly and monotonically associated with larger impacts, indicating that students may 'learn how to use' tutoring more effectively over time. Alternatively, students who access tutoring more frequently may possess inherent characteristics, such as higher baseline engagement, that render the tutoring more beneficial. In contrast, the proportion of student talk shows minimal associations with impact. This finding is directionally inconsistent with classic tutoring accounts that emphasize student explanation and constructive engagement as drivers of learning [5], and suggests that, in brief, problem-focused, on-demand chats, the quantity of student talk may be less informative than the specificity, timing, and instructional content of tutor moves. However, the crude metric of the proportion of words used by students vs. teachers does not capture the quality of the conversation; more work can be conducted in this area using the effect estimates from our framework. Together, these patterns point to a practical implication for embedded systems: effectiveness may depend less on maximizing interaction volume and more on ensuring sessions are long enough to resolve a misconception while supporting students in developing productive help-seeking routines.

Student-level heterogeneity shows larger benefits for learners with lower prior mastery, consistent with just-in-time support models and prior tutoring evidence [23]. However, low-SES students benefit slightly less on average and show a weaker mastery–impact gradient, aligning with prior work suggesting that on-demand tutoring may require complementary design supports to ensure equitable benefit [21, 9].

Finally, the robustness checks show both the value and the limits of using observational data to evaluate embedded tutoring interventions. When we used a broader control group, the estimated effects became smaller, but remained positive. This pattern suggests that the results are not driven by one specific control-group definition. At the same time, it shows how difficult it is to identify the right comparison group when tutoring happens at different moments over time and when earlier tutoring may affect later performance. These challenges underscore the importance of methods that account for students' changing knowledge states and include diagnostic checks, such as overlap and placebo tests, to assess possible remaining bias [35, 12].

8. LIMITATIONS & FUTURE WORK

Several limitations suggest directions for future research. First, although our identification strategy relies on conditional ignorability, sensitivity analyses indicate that unmeasured factors such as student motivation or teacher practices would need to be substantially stronger than our platform-derived measures to overturn the findings. Second, treating tutoring as a binary exposure masks variation in instructional quality and conversational strategy. Future work should use process-level data, such as transcripts or instructional moves, to identify the mechanisms driving effectiveness. Third, our proximal outcomes capture immediate impact and near transfer but not long-term learning gains. Future studies should examine whether session-level effects accumulate over time. Finally, because this study focuses on a single platform, future research should test the framework across domains, platforms, and designs that more directly examine equity and pedagogical mechanisms.

ABSTRACT

Accurately tracing a learner's knowledge state is a central challenge in many applications as it directly impacts educational downstream tasks such as recommendation, dropout prediction, and next-question correctness prediction. Prior research in learner modeling and knowledge tracing has shown that incorporating domain structure leads to more accurate estimates of learner knowledge, while parallel work has demonstrated that explicitly modeling epistemic uncertainty improves performance on these tasks. However, these two research directions have largely been explored independently. In particular, existing approaches rarely propagate uncertainty beyond the level at which learner evidence is directly observed, and domain-informed propagation strategies typically ignore uncertainty altogether. In this paper, we propose KT-DUSL, an uncertainty-aware learner model that jointly represents knowledge mastery, epistemic uncertainty, and domain structure within a unified framework. Building on subjective logic, we introduce a novel propagation policy that diffuses both mastery and uncertainty across the domain structure. This policy enables the model to better handle sparse interaction data. We evaluate KT-DUSL on large-scale datasets and show that propagating uncertainty through the domain structure yields improvements in next-question correctness prediction over uncertainty-agnostic and non-propagation-based baselines.

Keywords

knowledge tracing, learner modeling, uncertainty, mastery propagation, personal knowledge graphs

1. INTRODUCTION

A learner model aims at tracing learners' knowledge and can be understood as an explicit, machine-interpretable representation of an individual learner within an online learning environment [6]. The content of a learner model consists of a structured combination of learner data and inferred characteristics. Learner data includes relatively static attributes—such as demographic and educational background—as well as dynamic data derived from interactions with learning systems. Among the various learner characteristics that can be inferred from such data, the learner's knowledge state is the most commonly modelled, typically referred to as a knowledge model [30]. Learner models can be used as an internal component of an Intelligent Tutoring System (ITS) to trace the learners' knowledge, and to support downstream tasks such as recommendation, adaptive learning, and personalised feedback [32], or as a resource that can be exposed to the learner, for example through open learner models [9].

Learner models have recently come to include information about the domain as well, referred to as a domain model [30]. Concretely, the learning domain model includes learning items (exercises), knowledge components (KCs), and the relations between them [30]. While most early learner models assumed KCs to be independent, more recent work has increasingly explored structured representations of KCs and their relations, e.g. hierarchical or prerequisite relations [26]. This evolution reflects the intrinsic nature of educational domains, in which KCs are rarely isolated but are instead meaningfully connected. Incorporating domain structure naturally raises the question of propagating knowledge estimates within this structure. Since KCs are connected, evidence observed on one KC may carry implications for related KCs [36]. Existing approaches differ in how they address this propagation problem, ranging from expert-defined propagation rules to probabilistic propagation policies and, more recently, to neural network–based latent propagation [36, 20, 23]. Overall, taking domain structure into account has significantly improved the quality of knowledge models and, consequently, learner models [11].

In educational settings, learner interaction data are often sparse and unevenly distributed across KCs, leading to increased uncertainty—specifically, epistemic uncertainty—in knowledge estimates [13]. Throughout this paper, the term *uncertainty* is used to refer to epistemic uncertainty, i.e., uncertainty arising from limited evidence about a learner's mastery of a KC. It reflects how strongly a mastery estimate is supported by observations, and is reducible as more learner–KC interactions are collected. Prior work suggests that

quantifying uncertainty improves next-question correctness prediction by mitigating overconfident predictions, particularly when evidence is sparse [13, 25, 3]. In learner models, this uncertainty is rarely considered. Yet, some approaches quantify uncertainty when predicting the correctness of the next learner interaction [14, 25]. However, these approaches typically provide uncertainty estimates on unstructured sets of KCs.

In parallel, research on *open learner models* emphasises the importance of transparency and explainability in learner modeling by making aspects of the learner model explicit and consultable by the learner [9, 8]. Providing uncertainty estimates alongside mastery estimates further supports the idea of opening the learner model to the learner, as it enables her to better interpret, reflect on, and trust the information presented in the learner model.

In this context, our work aims to build a unified learner model that incorporates not only the domain structure, but also the learner's knowledge and associated uncertainty throughout this structure. We hypothesize that estimating uncertainty throughout the domain structure can improve the quality of the learner model. We raise the following research question:
RQ: Does incorporating the domain structure impact the learner model?
To answer this question, we raise two sub-research questions:
S-RQ1: How to propagate uncertainty alongside knowledge mastery within the domain structure?
S-RQ2: Under which settings does the domain structure provide the greatest benefits?

The rest of the paper is organized as follows. Section 2 reviews related work, with a particular focus on learner and domain modeling, the use of knowledge graphs in education, and mastery propagation within graph-structured representations. Section 3 presents KT-DUSL, a learner model that uses subjective logic to model knowledge mastery and uncertainty in a hierarchical domain structure. Section 4 describes the experimental setup, and Section 5 discusses the results. The code is publicly available at `https://github.com/anonymousreseach/KT-DUSL.git`.

2. RELATED WORK

This section reviews prior work related to our contribution. We first discuss learner and domain modeling approaches in ITSs. We then review the use of knowledge graphs in education. Finally, we examine existing approaches to knowledge mastery propagation and the quantification of uncertainty in learner models.

2.1 Learner and Domain Modeling

Learner modeling represents learners' abilities and behavior through interaction data [30, 19]. It supports personalization and instructional decision-making in ITSs [19].

Learner models may also capture affect, motivation, metacognition, or preferences [18, 32]. However, the dominant line of work focuses on modeling learners' mastery of knowledge concepts [16, 30]. This problem is commonly framed as *knowledge tracing*, which tracks latent knowledge over time to predict future performance [16, 31, 30].

Learner modeling is related to, but distinct from, *domain modeling* [18, 30]. Learner models encode the learner's current and evolving knowledge with respect to a domain, while domain models specify the content structure (items, knowledge components and relations) [27]. Domain models are often treated as relatively stable, but they can be refined from data when the initial structure is imperfect [10, 29]. In contrast, learner models are inherently dynamic, as each interaction updates knowledge mastery estimates and can incorporate learning and forgetting processes [16, 30].

Prior work varies in how domain and learner models are represented and coupled [18, 30]. Many systems keep the domain structure fixed (e.g., a predefined KCs mapping) and infer learner mastery on top of it [16, 15]. Other approaches learn or exploit dependencies between KCs to propagate learner-specific evidence or mastery estimates across related KCs [10, 26].

Beyond predictive accuracy, learner models also play an important role in explainability. In this context, research on *open learner models* emphasizes the importance of representations that make learner knowledge states explainable to both learners and instructors [9, 8]. Building on this principle, we adopt a learner model that explicitly represents both knowledge mastery and epistemic uncertainty within the domain structure. Such structured representations can, in principle, be exposed to learners to support reflection, self-regulated learning, and trust [9, 21]. In practice, KT-DUSL supports this by maintaining explicit, interpretable KC-level estimates of both mastery and uncertainty within the learner's PKG, which can be visualized (e.g., as a concept-level dashboard) or queried to provide feedback on uncertain areas. This allows learners and instructors to inspect not only what is known, but also where knowledge estimates remain uncertain, thereby supporting informed decision-making and targeted learning.

2.2 Knowledge Graphs

Knowledge graphs (KGs) are a widely used formalism for representing structured knowledge, where concepts are modeled as nodes and semantic relations between them as edges [1]. In educational systems, KGs have been extensively used to represent domain knowledge—often referred to as domain knowledge graphs, i.e., graph-based representations of domain models—in the form of concept maps, prerequisite graphs, or hierarchical concept structures [1]. Such a representation makes explicit the relationships between knowledge components and can be used to support curriculum design, content sequencing, and learner assessment [18].

In most educational applications, domain knowledge graphs are shared across learners and capture expert-defined domain structure [17]. Learner modeling is then performed on top of this structure by associating learner-specific information -such as knowledge mastery estimates- with individual knowledge components. While effective, this separation typically treats the domain structure as static and limits the extent to which learner knowledge can be jointly reasoned about and updated across the graph, as learner evidence is incorporated locally rather than being propagated through the domain structure [34].

More recently, knowledge graphs have been extended toward learner-centered representations, giving rise to the notions of personalized and personal knowledge graphs. Personalized knowledge graphs typically adapt an existing general-purpose or domain-level KG by filtering, weighting, or annotating entities and relations according to a user's preferences or profile [5]. In contrast, personal knowledge graphs (PKGs) exist alongside other KGs and contain a disjoint set of entities that are of direct relevance to a single individual, while optionally linking to external knowledge graphs [33].

Different definitions of PKGs emphasize complementary aspects of the concept. From an ownership and access-control perspective, a PKG is a knowledge graph fully controlled by an individual, with the primary goal of supporting personalized services [33]. From a semantic perspective, PKGs represent structured knowledge about entities and relations of personal relevance, organized around a central user node [5].

In educational contexts, PKGs provide a natural foundation for learner-centered modeling, as they allow domain knowledge to be explicitly organized around the learner. Ain et al. [2] propose a PKG-based learner modeling approach in which learners construct their own PKGs by marking concepts they did not understand while interacting with learning items. More recently, Alatrash et al. [4] leverage PKGs in combination with graph neural networks to model learner knowledge mastery in a transparent manner, demonstrating the potential of graph-based representations for learner modeling.

Despite these advances, most PKG-based educational approaches attach learner state to graph nodes in a static or ad-hoc manner, typically as scalar mastery values or latent embeddings, offering limited support for principled propagation of learner knowledge and uncertainty across the graph.

2.3 Mastery Propagation through the Domain Structure

A substantial body of work goes beyond estimating mastery independently per KC and instead propagates learner evidence through a domain structure.

Early educational systems commonly relied on learner models coupled to concept networks, in which prerequisite or semantic links define hand-crafted propagation rules: evidence of mastery or failure on one KC is deterministically or heuristically propagated to related KCs. Such approaches rely on expert-defined rules and propagation strengths, resulting in transparent but largely fixed propagation behavior [7].

A second line of work embeds the domain structure directly into probabilistic graphical models, where KC mastery variables are treated as latent states and evidence is propagated through structured dependencies. Under tree-structured hierarchies, Gao et al. [20] propose KT^2, which models concept mastery using a Hidden Markov Tree to propagate evidence along parent-child relations. Beyond trees, Bayesian networks and dynamic Bayesian networks represent more general KC topologies, allowing updates on one KC to influence related prerequisites or successors [22]. Related formulations further introduce learner-specific factors or jointly infer prerequisite structure from interaction data [28, 12].

More broadly, probabilistic approaches to learner modeling have long leveraged Bayesian networks to represent dependencies between KCs and to reason under uncertainty [15]. Millán et al. [24] provide a general framework for engineering Bayesian student models, illustrating how conditional dependencies between concepts enable evidence propagation and learner knowledge mastery updates.

Finally, some deep knowledge tracing models incorporate domain structure using graph neural networks and perform inference through message passing on KC graphs or question-KC bipartite graphs [26, 34]. GIKT further leverages graph convolution to exploit higher-order question-KC relations and mitigate data sparsity [35]. While effective in terms of predictive performance, these approaches operate on latent embeddings and generally lack explicit, interpretable KC-level mastery estimates.

Uncertainty Modeling and Propagation. Although many learner models rely on probabilistic formulations, uncertainty is typically treated implicitly rather than explicitly represented in the learner model. As a result, mastery estimates are often reduced to point values, conflating low mastery due to consistent failure with low mastery arising from limited evidence. Moreover, most propagation policies focus on transferring mastery alone, without modeling how epistemic uncertainty should evolve across structured representations. These limitations are particularly problematic in sparse settings, motivating learner models that jointly represent and propagate both knowledge mastery and uncertainty.

3. INTEGRATING THE DOMAIN STRUCTURE IN A LEARNER MODEL

In this work, we introduce KT-DUSL, a new learner model that explicitly leverages the domain structure, and relies on a dedicated propagation policy to quantify both knowledge mastery and uncertainty throughout this structure. Before presenting the KT-DUSL model, we first recall propagation policies commonly used in the literature.

3.1 Propagation in a Domain Structure

Learner models that manage a domain structure rely on propagation policies. Most works in the literature aim at propagating knowledge mastery throughout the knowledge components (KCs) of the domain. Two general principles govern such a propagation: (i) information should be attenuated as it moves away from its source, and (ii) information originating from multiple sources should be combined coherently. These principles are commonly implemented through a discount operator and a consensus operator. We introduce these operators in a general setting. They will then be instantiated in KT-DUSL.

Discount Operator. The discount operator models the attenuation of information during propagation across the domain structure. A discount factor $r_{i,j} \in [0, 1]$ controls the strength of propagation from a KC c_i to another KC c_j.

Consensus Operator. When a KC receives information from multiple related KCs, these sources of information must be aggregated in a principled manner. The consensus operator

defines how multiple propagated pieces of information are combined.

3.2 The KT-DUSL Learner Model

KT-DUSL is a learner model that is designed to manage simultaneously the domain structure and the learner's mastery and associated uncertainty throughout this structure. KT-DUSL relies on two core elements: (i) a Personal Knowledge Graph (PKG), instantiated for each learner, (ii) subjective logic to estimate knowledge mastery and associated uncertainty. The originality of KT-DUSL lies in the propagation policy used to propagate these quantities throughout the domain structure. KT-DUSL also supports explainability by maintaining explicit KC-level knowledge mastery and uncertainty estimates within the PKG, whose updates can be made visible to the learner.

From now on, the general term exercise will be used to refer to a learning item.

3.2.1 Personal Knowledge Graph Structure

KT-DUSL relies on a dedicated *Personal Knowledge Graph* (PKG), constructed for each learner, that jointly represents (i) the domain structure, made up of both a hierarchy of *knowledge components* (KCs) where higher-level KCs correspond to broader concepts and leaf-level KCs capture more fine-grained concepts, and the set of exercises linked to leaf-level KCs, (ii) learner–exercise interactions, and (iii) learner-specific estimates of knowledge mastery and uncertainty on the KCs of the domain structure.

Let $PKG_l = (V, E)$ denote the personal knowledge graph of learner l. The set of nodes is defined as $V = C \cup X \cup \{l\}$, where C is the set of knowledge components, X is the set of exercises, and l denotes the node that represents the learner. E represents the set of edges. Each $(c_p, c_c) \in E$ encodes hierarchical membership relations between KCs. Each exercise $x \in X$ is associated with a set of KCs $C(x) \subseteq C$. The learner node is connected to each exercise node through the observed interaction outcome, and to each KC through the learner's current knowledge mastery and uncertainty estimates for that KC.

3.2.2 Subjective Logic to Estimate Mastery and Uncertainty of KCs

In the recent literature, the KT-USL learner model [3], has proposed to use subjective logic to trace learners' knowledge mastery and uncertainty on KCs.

At time t, the knowledge state of learner l on $c_i \in C$, is represented by $\omega_t(l, c_i)$, a subjective logic (SL) opinion:

$$\omega_t(l, c_i) = \big(b_t(l, c_i),\ d_t(l, c_i),\ u_t(l, c_i),\ a\big), \tag{1}$$

where $b_t(l, c_i)$, $d_t(l, c_i)$, and $u_t(l, c_i)$ denote belief in mastery, disbelief, and epistemic uncertainty, respectively, with $b_t(l, c_i) + d_t(l, c_i) + u_t(l, c_i) = 1$ and a is a base-rate prior.

Opinions are grounded in accumulated interaction evidence $(r_t(l, c_i), s_t(l, c_i))$, corresponding to the number of correct and incorrect responses observed for learner l on c_i. Following subjective logic, belief, disbelief, and uncertainty are computed as:

$$b = \frac{r}{r + s + W}, \qquad d = \frac{s}{r + s + W}, \qquad u = \frac{W}{r + s + W},$$

where $W > 0$ is a prior weight that controls the contribution of epistemic uncertainty under sparse evidence. The knowledge mastery estimate $m_t(l, c_i)$ is defined as the expected value of the opinion and ranges between 0 and 1.

$$m_t(l, c_i) = b_t(l, c_i) + a \cdot u_t(l, c_i), \tag{2}$$

This formulation explicitly distinguishes between low mastery supported by substantial evidence and low mastery arising from insufficient information, while remaining local to individual (learner, concept) pairs.

It is important to note that this formulation captures epistemic uncertainty arising from limited learner–KC evidence. Other sources of uncertainty may also affect learner modeling, including noisy or incomplete exercise–KC mappings, rarely accessed concepts, or inaccuracies in the domain structure. These sources are not explicitly modeled in KT-DUSL, which assumes a fixed and reliable domain structure. Therefore, the uncertainty quantified in this work should be interpreted as evidence-based epistemic uncertainty rather than a comprehensive account of all uncertainty sources.

3.2.3 Mastery and Uncertainty Propagation in KT-DUSL

KT-DUSL extends the KT-USL model, by explicitly leveraging the domain structure. KT-DUSL relies on a propagation policy for both mastery and uncertainty across KCs of the structure. More precisely, KT-DUSL propagates information between hierarchically related KCs. This propagation allows the learner model to compensate for sparse or unevenly distributed evidence.

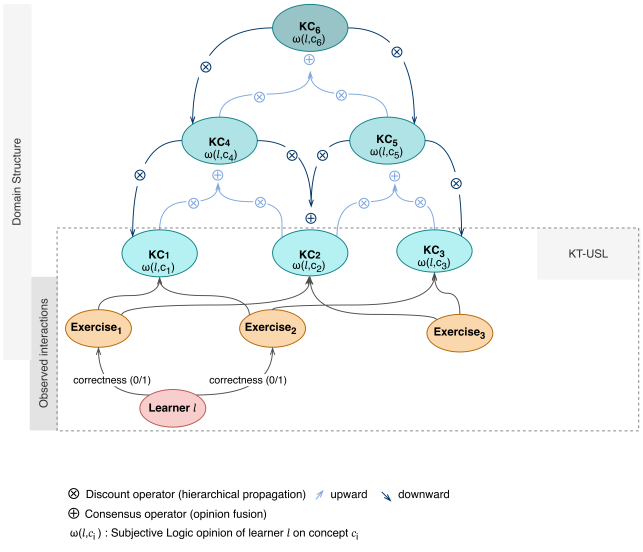

Figure 1: Overview of an example PKG and the KT-DUSL updating process.

KT-DUSL relies on PKG_l, the Personal Knowledge Graph of a learner l, where the nodes of PKG_l represent the KCs of the domain, the exercises and the learner l. Figure 1

represents an example of PKG_l, where blue nodes represent the KCs of the domain, orange nodes represent the exercises and the pink node represents the learner. The edges of the PKG encode three types of relations: hierarchical relations between KCs, relations between exercises and leaf-level KCs and relations between the learner and the exercises.

KT-DUSL operates in an online setting. First, at time t, a learner-exercise interaction generates new evidence that updates learner-exercise links (lower part of Figure 1).
Second, KT-DUSL relies on the KT-USL model [3] to update the subjective logic opinion of leaf-level KCs c_i, denoted $\omega_t(l, c_i)$, from the previous opinion $\omega_{t-1}(l, c_i)$. Recall that from this opinion, the learner's mastery and uncertainty on these leaf-level KCs can be inferred (see Equation 2). When a KC is associated with multiple exercises (in the case of batch processing of interactions), evidence is extracted from all associated exercises. The opinion on this KC is then calculated using this evidence.
Third, a specific propagation policy is performed across the hierarchy (relations between blue nodes in Figure 1). The main contribution of KT-DUSL lies in this propagation policy. It relies on the discount and consensus operators presented in Section 3.1. KT-DUSL instantiates these operators using subjective logic.

In KT-DUSL we propose to distinguish between two propagation directions: *upward* propagation, i.e., from a KC to hierarchically higher KCs, and *downward* propagation, i.e., from a KC to hierarchically lower KCs. Upward propagation is performed first, then downward propagation is performed. These two directions are governed by distinct discount rates, $r^{\uparrow}$ and $r^{\downarrow}$. In KT-DUSL an opinion on c_i can be propagated only from c_i to a directly related KC c_j. This opinion is first *discounted* as follows:

$$\omega_t(l, c_i \to c_j) = \omega_{t-1}(l, c_i) \otimes r_{i,j}. \tag{3}$$

where $r_{i,j}$ denotes the discount rate associated with the hierarchical relation from c_i to c_j ($r_{i,j}$ takes one of the two values among $r^{\uparrow}$ and $r^{\downarrow}$), and controls how much belief and disbelief are transferred, with the remaining mass assigned to epistemic uncertainty.

Considering recipient KCs, a KC c_i may receive multiple discounted opinions. In KT-DUSL, these opinions come from its related KCs in the hierarchy. Let $\Omega_t(l, c_i)$ denote the set of all opinions propagated to c_i at time t. Second, the opinion is updated using the subjective logic *consensus* operator:

$$\omega_t^{\text{prop}}(l, c_i) = \bigoplus_{s \in \Omega_t(l, c_i)} s. \tag{4}$$

The choice of this consensus operator comes from its ability to weight the contribution of different opinions according to their uncertainty. It ensures that opinions supported by stronger evidence exert greater influence on c_i.

To summarize, after each learner-exercise interaction, KT-DUSL performs: (i) a local update of the opinions of the leaf-level KCs associated with the exercise of the newly observed evidence using KT-USL; and (ii) a propagation step that diffuses mastery and uncertainty throughout the domain hierarchy (up and down). Propagation relies on both discount and consensus operators. As a result, the learner's PKG evolves over time to reflect both accumulated evidence and structural relations between concepts.

Algorithm: KT-DUSL update
Input: Learner-exercise interaction (l, x), PKG_l
Output: Updated opinions $\{\omega(l, c)\}$ in the learner's PKG

Identify the set $C(x)$ of leaf-level KCs of exercise x
Extract evidence from the interaction (l, x)

// leaf-level KC mastery and uncertainty evaluation
for each $c \in C(x)$ **do**
  Update the observed opinion ω_c^{obs} using KT-USL
end for

// discount, upward propagation
for each $c \in C(x)$ **do**
  Propagate $\omega_{c_i}^{\text{obs}}$ upward to higher-level KCs using $r^{\uparrow}$
  Update $\omega_t(l, c)$ with opinion from $t-1$ via consensus
end for

// discount, downward propagation
for each KC updated by upward propagation **do**
  Propagate opinion downward to lower-level KCs using $r^{\downarrow}$
  Update $\omega_t(l, c)$ via consensus
end for

4. EXPERIMENTAL SETUP

4.1 Datasets

To evaluate KT-DUSL, we perform experiments on two datasets from the literature. Both datasets are related to mathematics.

Junyi. The Junyi dataset is derived from an online educational platform that provides large-scale logs of student interactions with mathematical questions.[1]

EEDI (Task 1-2). EEDI is an online mathematics learning platform that provides interaction logs together with rich metadata describing questions, learners, and answers.[2]

Table 1 summarizes the main characteristics of the two datasets. A key structural difference between them has motivated their choice: in Junyi, each exercise is associated with a single KC, whereas in EEDI each exercise is associated to multiple KCs, with an average of 4.17 concepts per question. As a result, EEDI is denser than Junyi with on average about twice as many interactions per concept. We investigate if these differences affect the impact on the mastery and uncertainty, as well as the performance on downstream tasks.

4.2 Metrics

We quantify the impact of the dedicated domain-informed propagation on the learner model. Concretely, we measure

[1] `https://www.kaggle.com/datasets/junyiacademy/learning-activity-public-dataset-by-junyi-academy`
[2] `https://www.kaggle.com/datasets/alejopaullier/eedi-external-dataset`

Table 1: Characteristics of the Junyi and EEDI datasets.

Statistic	Junyi	EEDI
Interaction data		
# Learners (unique)	72,758	118,971
# Exercises	1,330	27,613
# Learner–exercise interact.	16,217,311	15,867,850
KCs		
# Number of KCs	224	388
Average # KCs per exercise	1.00	4.17
Average # interact. per KC	94.8k	200k
Hierarchy structure		
Max depth	3	3
# levels	4	4
# KCs at depth 1/2/3	10/42/171	9/69/308

the absolute change in knowledge mastery and uncertainty, induced by propagation on leaf-level KCs, defined as $|\Delta| = |x_{\text{with domain}} - x_{\text{without domain}}|$. Absolute deltas are reported for mastery (KT-A → KT-DA and KT-USL → KT-DUSL) and for uncertainty (KT-USL → KT-DUSL).

In line with the literature, we also evaluate KT-DUSL on the traditional next-question correctness prediction task, using the following standard metrics:

- **AUC** (Area Under the ROC Curve), which measures the quality of probabilistic ranking independent of a fixed decision threshold.
- **Accuracy@0.5**, computed by thresholding predicted correctness probabilities at 0.5.
- **LogLoss**, which assesses the calibration and sharpness of predicted probabilities. The lower, the better.

4.3 Baseline Models

To address the RQ raised in the introduction, we empirically evaluate KT-DUSL, and compare it against a set of baseline models. This evaluation will contribute to quantifying the effects of both uncertainty modeling and propagation policy.

KT-A is a deterministic baseline model that estimates learner mastery for leaf-level KCs by averaging observed correctness outcomes. It does not quantify uncertainty and does not exploit domain structure.

KT-DA extends **KT-A** by propagating average mastery estimates across the KC hierarchy using mean-based instantiations of the discount and consensus operators.

KT-USL (see Section 3.2.2) models learner mastery for leaf-level KCs only, and quantifies uncertainty using subjective logic. KT-USL treats each KC independently, so does not propagate information across the domain structure.

4.3.1 Parameter Initialization and Control

KT-DUSL introduces parameters governing both propagation and subjective logic. The coefficients $r^{\uparrow}$ and $r^{\downarrow}$ control the strength of upward and downward propagation in the domain hierarchy, while the subjective logic formulation relies on the base rate a and the non-informative prior weight W. Although several parameter settings were explored on a validation set, we report results for fixed values due to space constraints: $r^{\uparrow} = r^{\downarrow} = 0.8$, $a = 0.5$, and $W = 2.0$, which corresponds to the best-performing configuration.

5. EVALUATION OF THE IMPACT OF THE DOMAIN STRUCTURE

In this section we evaluate the impact of the domain structure on the learner model, and on the performance of a downstream task, including in high uncertainty settings.

5.1 Impact on the Learner Model

We start by analyzing the impact of domain-informed propagation on both knowledge mastery and uncertainty. Table 2 reports the median and quartiles of the absolute changes induced across different datasets. Recall that Junyi and EEDI mainly differ in the average number of KCs per exercise. To make the datasets more comparable, we construct a third dataset, which is a mono-concept version of the EEDI dataset, by retaining a single leaf concept per exercise. This concept is selected deterministically by first choosing the deepest associated KC in the hierarchy (i.e., the most specific concept), and mapping it to a leaf node when necessary.

Table 2: Median and quartiles of the absolute changes induced by domain-informed propagation.

Absolute Delta	Q1	Median	Q3
Junyi dataset			
$\|\Delta\|$ Mastery ($m_t(l,c)$) (KT-A → KT-DA)	**0.053**	**0.107**	**0.164**
$\|\Delta\|$ Mastery (KT-USL → KT-DUSL)	0.001	0.004	0.015
$\|\Delta\|$ Uncertainty (KT-USL → KT-DUSL)	0.002	0.008	0.034
EEDI mono-concept dataset			
$\|\Delta\|$ Mastery (KT-A → KT-DA)	**0.032**	**0.107**	**0.204**
$\|\Delta\|$ Mastery (KT-USL → KT-DUSL)	0.007	0.032	0.064
$\|\Delta\|$ Uncertainty (KT-USL → KT-DUSL)	0.036	0.095	0.192
EEDI multi-concept dataset			
$\|\Delta\|$ Mastery (KT-A → KT-DA)	**0.022**	**0.050**	**0.084**
$\|\Delta\|$ Mastery (KT-USL → KT-DUSL)	0.009	0.023	0.052
$\|\Delta\|$ Uncertainty (KT-USL → KT-DUSL)	**0.055**	**0.124**	**0.241**

Let us first consider the impact of integrating the domain structure, on the knowledge mastery. Recall that knowledge mastery ranges between 0 and 1, hence also the impact. Integrating the domain structure in a model that does not manage uncertainty (KT-DA vs. KT-A), has a significant impact on the knowledge mastery in a mono-concept setting, with a median of impact equal to 0.107. On EEDI, Q3 is

equal to 0.204, which means that the impact is larger than 20 points of percentage for 25% of the concepts. Yet, this impact is twice lower in a multi-concept setting. Managing domain structure on uncertainty-aware learner models (KT-DUSL vs. KT-USL) impacts the knowledge mastery to a lower extent (median around 0.03 on all datasets).

Focusing on the change in uncertainty on the KCs, the impact is larger on EEDI (both settings) than on Junyi. The highest impact is obtained on the multi-concept setting (median equal to 0.124 and Q3 is equal to 0.241). Recall that this large impact on uncertainty occurs in a context of small impact on knowledge mastery.

We can conclude that on a mono-concept setting, KT-DA impacts significantly more the knowledge mastery than KT-DUSL. Besides, KT-DUSL impacts more uncertainty in multi-concept settings.

Based on these conclusions we wonder if these significant changes in knowledge mastery and uncertainty translate into improved performance on a downstream task.

5.2 Impact on the Next-Question Correctness Prediction Task

In this section, we aim at evaluating the impact of the domain structure on a downstream task. In particular, we choose to evaluate on the next-question correctness prediction task.

5.2.1 Overall Impact

To evaluate the overall impact of the domain structure on the next-question correctness prediction task, we use the three metrics introduced in section 4.2, namely AUC, ACC@0.5 and LogLoss.

We first consider Junyi dataset. Evaluation metrics values are displayed in Table 3.

Table 3: AUC, ACC@0.5 and LogLoss on Junyi dataset.

Model	AUC	ACC@0.5	LogLoss
KT-A	0.702	0.728	1.178
KT-USL	0.705	0.728	0.556
KT-DA	0.702	0.728	0.575
KT-DUSL	**0.710**	**0.729**	**0.551**

The impact of the exploitation of the domain structure can be evaluated by comparing two pairs of models. First, we compare models that manage KC knowledge mastery only, concretely KT-A and KT-DA. The domain structure has no effect on AUC or accuracy but improves LogLoss significantly. The effect on AUC is thus not related to the significant impact on knowledge mastery (see Section 5.1). Second, we compare models that quantify and manage uncertainty, concretely KT-USL and KT-DUSL. KT-DUSL achieves slightly higher performance, particularly in AUC (0.705 to 0.710) and LogLoss (0.556 to 0.551). Here again, the impact on knowledge mastery was null. Overall, we can say that exploiting the domain structure and propagating mastery and uncertainty through this structure remains beneficial when used with an uncertainty-aware model, although the impact on the learner model is limited.

Let us now examine whether these conclusions hold on the EEDI dataset, in which each exercise is associated with multiple KCs. Performance is displayed in Table 4.

Table 4: AUC, ACC@0.5 and LogLoss on EEDI dataset.

Model	AUC	ACC@0.50	LogLoss
KT-A	0.723	0.693	0.620
KT-USL	**0.730**	**0.696**	0.578
KT-DA	0.722	0.692	0.587
KT-DUSL	0.729	0.695	**0.576**

On this dataset, the domain structure does not consistently improve these metrics. Indeed, KT-DUSL does not improve AUC and accuracy, and only slightly improves LogLoss. We hypothesize that this is due to the multi-concept setting, in which much of the relational information between concepts is implicitly captured through the exercise-KC associations. As a consequence, the explicit relation provided by the domain structure is already present in the data. This is in line with the limited impact on knowledge mastery from the previous section.

To test this hypothesis, we perform similar evaluation on the mono-concept version of the EEDI dataset, The associated performance is reported in Table 5.

Table 5: AUC, ACC@0.5 and LogLoss on mono-concept EEDI dataset.

Model	AUC	ACC@0.50	LogLoss
KT-A	0.667	0.676	3.043
KT-USL	0.680	0.676	0.616
KT-DA	0.686	0.680	0.620
KT-DUSL	**0.702**	**0.683**	**0.601**

We can see that, as on Junyi, considering the domain structure improves performance. KT-DUSL consistently outperforms all baseline models across AUC, ACC@0.50, and LogLoss, with particularly large gains over KT-USL (AUC 0.680 to 0.702; LogLoss 0.616 to 0.601). This tends to show that, in the context of mono-concept datasets, that can be associated to sparse data, the domain structure contributes to the quality of the learner model. More precisely, the quality of downstream next-question correctness prediction task is increased. This thus supports our hypothesis.

These experiments highlight two important conclusions: 1) quantifying uncertainty is broadly beneficial across datasets, 2) considering the domain structure has a context-dependent impact. If the relations between KCs are already implicitly encoded in the dataset (such as multiple KCs per exercise), domain-informed propagation does not provide additional information, so does not improve the performance. In contrast, in the context of sparse data (single concept per exercise), the domain structure contributes to improve the performance.

These findings lead us to investigate deeper the relation between the amount of data available, the uncertainty and performance. Concretely, we wonder if 1) the domain structure is more beneficial in the context of limited information

about the learner, 2) the domain structure is more beneficial in high uncertainty settings.

5.2.2 Limited Evidence Settings

In this section, we analyze the benefits of incorporating the domain structure under different levels of available evidence per learner-concept pair by comparing KT-USL and KT-DUSL. The amount of evidence is quantified by k, the number of past interactions a learner had with a given KC. Concretely, k denotes the interaction index for a learner-KC pair: $k = 1$ corresponds to the learner's first encounter with the KC, $k = 2$ to the second interaction, and so on.

Table 6: Performance by evidence count k on Junyi (P1, exact mode, global).

k	Method	n	AUC	ACC@0.50	LogLoss
1	Leaf-SL	484,455	0.500	**0.676**	0.693
	Prop-SL	484,455	**0.557**	**0.676**	**0.656**
3	Leaf-SL	449,388	0.655	**0.743**	0.588
	Prop-SL	449,388	**0.674**	0.741	**0.569**
5	Leaf-SL	425,942	0.689	0.759	0.543
	Prop-SL	425,942	**0.700**	**0.760**	**0.532**
10	Leaf-SL	340,884	0.707	0.740	0.538
	Prop-SL	340,884	**0.711**	**0.742**	**0.535**
20	Leaf-SL	241,172	0.716	0.737	0.539
	Prop-SL	241,172	**0.718**	**0.738**	**0.537**

Table 6 reports AUC, ACC@0.5 and LogLoss for different values of k. Higher values of k correspond to smaller dataset sizes. We can see that KT-DUSL consistently outperforms KT-USL on the three metrics, whatever is the value of k. The largest gains are observed with low values of k, i.e. with little evidence.

For $k = 1$, incorporating domain structure yields a substantial improvement in AUC (11% improvement, from 0.500 to 0.557) and a notable reduction in LogLoss (5.3% improvement, from 0.693 to 0.656). This indicates that when little information about the learner is available, better discrimination and probability calibration are reached. As evidence accumulates ($k = 3$ and $k = 5$), the performance gap narrows but remains consistent, suggesting that the domain structure continues to provide complementary information beyond local evidence. For larger values of k ($k \geq 10$), difference in performance between the two models is almost null, reflecting the fact that the structure becomes marginal as evidence increases.

Overall, these results indicate that domain-informed propagation is most beneficial in the context of low evidence, where it contributes to effectively compensate for sparse learner–KC interactions. Its impact attenuates as evidence increases.

Let us now study to what extent these conclusions hold on EEDI dataset (mono-concept and multi-concept). Table 7 shows performance on the mono-concept EEDI dataset. As on Junyi, domain-informed propagation is consistently beneficial across all evidence levels. For small values of k, KT-DUSL yields large gains over KT-USL, particularly in AUC (19% improvement, from 0.500 to 0.594 for $k = 1$) and LogLoss (4% improvement, from 0.693 to 0.666). As on Junyi, as k increases, improvements decrease for all metrics. This confirms the importance of domain structure when evidence is low and becomes useless when evidence increases.

Table 7: AUC, ACC@0.5 and LogLoss according to the amount of evidence per (learner, concept) pair on EEDI (mono-concept) dataset.

k	**Method**	n	**AUC**	**ACC@0.50**	**LogLoss**
1	KT-USL	461,224	0.500	0.619	0.693
	KT-DUSL	461,224	**0.594**	**0.630**	**0.666**
3	KT-USL	216,016	0.670	0.671	0.624
	KT-DUSL	216,016	**0.704**	**0.681**	**0.609**
5	KT-USL	131,670	0.711	0.691	0.593
	KT-DUSL	131,670	**0.730**	**0.698**	**0.582**
10	KT-USL	48,739	0.751	0.716	0.559
	KT-DUSL	48,739	**0.759**	**0.719**	**0.553**
20	KT-USL	8,037	0.757	0.725	0.538
	KT-DUSL	8,037	**0.761**	**0.727**	**0.535**

On the multi-concept EEDI dataset, we observe a markedly different behavior. The benefits of domain-informed propagation are almost null, whatever is the amount of evidence. We choose to not show values here. This confirms again the hypothesis drawn in section 5.2.1, the multi-concept setting implicitly encodes the domain structure, making the explicit domain structure useless. This is true even when evidence is low.

5.2.3 High Uncertainty Settings

We now intend to evaluate the benefits of incorporating the domain structure considering different uncertainty values. To this aim, we evaluate the impact of uncertainty on predictive performance, and in particular on AUC. Figures 2 and 3 show the AUC computed over sliding windows of 200,000 interactions, where each point corresponds to the average uncertainty of leaf KCs within a window, for the Junyi and mono-concept EEDI datasets. In both datasets, performance is consistently lower with high uncertainty values (30% decrease when uncertainty equals 1.0 compared to the case where uncertainty equals 0.0). This reflects the intrinsic difficulty of the prediction task in high uncertainty settings. However, in both datasets, KT-DUSL outperforms KT-USL when uncertainty is larger than 0.3. The higher the uncertainty, the larger the increase. When uncertainty is maximal (1.0), this increase reaches 12% and 18% on Junyi and EEDI respectively. This confirms the relevance of managing domain structure in uncertainty-aware models in the context of high uncertainty.

The previous two sections have highlighted the fact that the domain structure contributes to improve the performance on the next-question correctness prediction downstream task. This effect is particularly pronounced in low-evidence and high-uncertainty settings, where the domain structure contributes the most. The strong relation between evidence and uncertainty values is clearly stated thanks to these experiments.

These results allow us to answer the research questions in-

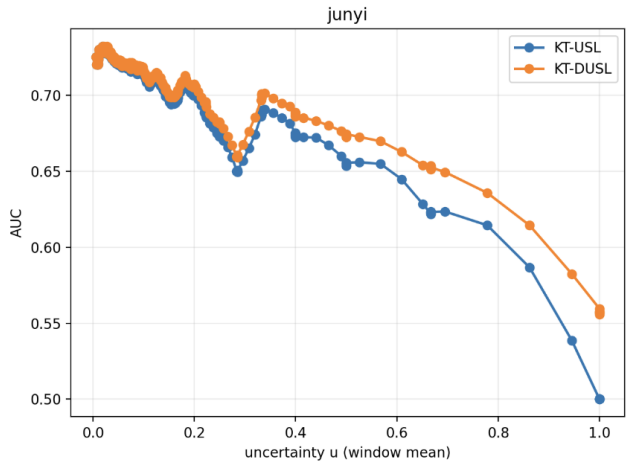

Figure 2: Sliding-window AUC of KT-USL and KT-DUSL as a function of uncertainty on the Junyi dataset.

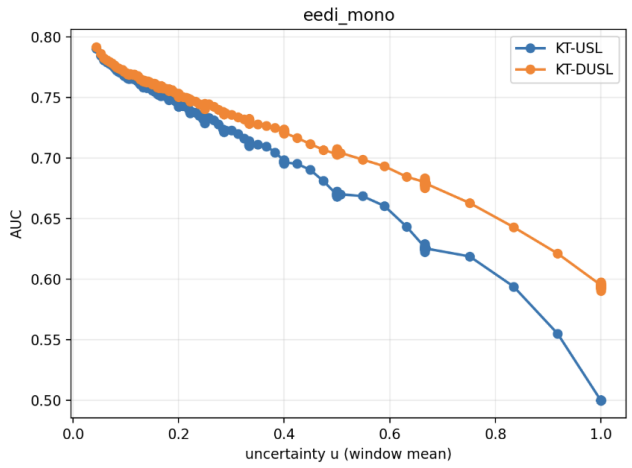

Figure 3: Sliding-window AUC of KT-USL and KT-DUSL as a function of uncertainty on the EEDI (mono-concept) dataset.

troduced in Section 1. Incorporating the domain structure actually impacts both the learner model and downstream prediction performance, thereby addressing S-RQ1. In particular, domain-informed propagation is most beneficial in settings characterized by high uncertainty or limited evidence, while its contribution becomes marginal when sufficient learner-KC information is available, thus addressing S-RQ2.

6. CONCLUSION

In this work, we studied the relevance of managing domain structure in learner models and associated downstream tasks. To this aim, we introduced KT-DUSL, a domain-informed learner model that jointly represents and propagates knowledge mastery and associated uncertainty in a learner model. Building on subjective logic, KT-DUSL performs local evidence updates and then propagates the resulting opinions through the domain structure, using discounting and consensus operators, thereby preserving uncertainty throughout the process.

Experiments on two mathematics-related datasets: Junyi and EEDI show that explicit uncertainty modeling consistently improves next-question correctness prediction, especially in AUC and LogLoss. We further find that, in the context of mono-concept exercises, domain-informed propagation provides the largest gains in high-uncertainty and low evidence per learner-concept pair settings. In contrast, in the multi-concept EEDI setting, hierarchical propagation brings limited benefit, suggesting that rich exercise-concept information encodes substantial relational information, and provides as much information as the domain structure.

Future work will leverage the joint propagation of knowledge mastery and epistemic uncertainty to develop an adaptive learning system that is guided by both estimated mastery and uncertainty within the domain structure. We also plan to investigate privacy-preserving deployments, in particular through federated learning, where learners' personal knowledge graphs are maintained locally and only a limited set of shared parameters is exchanged, thereby enabling collaborative learning.

ABSTRACT

LLM-based chatbots are increasingly used as on-demand tutors in computer science education, yet evaluating pedagogical effectiveness remains difficult because rubric scoring is costly and raw aggregates confound response quality with rater severity, criterion difficulty, and student-query context. We propose a Bayesian explanatory many-facet Rasch model (MFRM) that places rubric-criterion endorsements on a common logit scale and decomposes ratings into latent response quality, criterion difficulty, and rater severity, while incorporating query-level covariates as criterion-specific effects. Applied to 249 CodeHelp exchanges from a large undergraduate C++ course, double-coded by two experts on mistake identification, mistake location, guidance, accuracy of guidance, and correctness of next steps, the model indicates minimal systematic rater differences and pronounced criterion-difficulty gaps. Diagnosis criteria are the most difficult to satisfy, whereas accuracy and next-step criteria are the easiest. Input sufficiency yields modest, criterion-dependent shifts in endorsement probability, and topic patterns are explored descriptively, underscoring that observed tutoring quality depends on what students provide and the type of help they request.

Keywords

educational chatbots; large language models; pedagogical effectiveness; Many-facet Rasch Model

1. INTRODUCTION

LLM-based chatbots, also referred to as conversational agents, are increasingly deployed as on-demand tutors across K–12 and higher education in a wide range of domains [28, 33]. In computer science education in particular, a growing body of work reports benefits for programming-focused learning tasks, including answering students' questions [36], supporting learning of core programming concepts [32], and assisting with assessment or performance feedback [12, 49]. Unlike earlier chatbots that relied on scripted rules or narrow task-specific models, LLM-based chatbots are *generative*, with an enhanced capacity to produce open-ended, context-sensitive explanations and guidance specific to a learner's prompt. Recent studies have therefore examined a range of LLM-powered tools, including general-purpose models (e.g., GPTs) and code-specialized assistants (e.g., Codex- and Copilot style systems), with emerging evidence that these tools can reshape both pedagogical interactions (e.g., debugging support, conceptual explanation) and assessment-related practices (e.g., feedback generation and evaluation) [55, 19].

At the same time, rapid adoption has intensified the need for rigorous evaluation frameworks that can determine not only whether these systems work, but also how, for whom, and under what conditions they support learning and meaningful educational interactions [21, 1, 28]. To date, evaluation evidence is often assembled by triangulating quantitative outcomes, ranging from proximal indicators such as student completion or engagement [41, 17] to more distal outcomes such as learning gains, together with qualitative analyses including error coding, interaction reviews, and feedback from students and instructors [62, 8, 53]. Complementing these outcome-focused approaches, studies increasingly emphasize pedagogically grounded indicators such as alignment with curriculum standards [3], adaptability to individual learner needs [27], and support for higher-order thinking [14, 57, 8]. Collectively, this literature underscores that chatbot effectiveness is multi-dimensional and should not be reduced to a single score or outcome [31].

However, translating this multi-dimensional view into scalable measurement at the level where tutoring actually occurs, namely, the response and interaction level, remains challenging. In practice, pedagogical effectiveness is still most often judged through expert human annotation, typically via rubric-based scoring of chatbot responses or full interaction transcripts [61, 20, 37]. To improve scalability, recent computational work has explored automated proxies, including reference-based overlap measures (e.g., BLEU, METEOR, ROUGE) and reference-free confidence and similarity scores [10]. However, there is growing concern that these metrics provide limited pedagogical insight [37]. Although they can capture surface properties such as fluency or lexical overlap, they do not directly assess whether a chatbot adapts instruction to a learner's needs, detects misconceptions, or supports conceptual understanding. This creates a practical tension: expert evaluation remains necessary for pedagogically consequential judgments, yet it is costly and difficult to interpret at scale.

Recent work has also begun to apply Rasch-family models to structure LLM evaluation. Some studies treat chatbots as "examinees" and use Rasch analysis to benchmark model performance relative to item difficulty in test-like formats [7]. Other work uses many-facet Rasch models in human rating systems, often to quantify severity, consistency, or bias when LLMs act as automated scorers or raters [59, 23, 26, 34]. While valuable, these applications do not directly address the most common educational tutoring evaluation setting, in which experts apply pedagogically grounded rubrics to open-ended responses and scores must be interpreted under rater variability, uneven criterion difficulty, and systematic differences in query context.

Against this backdrop, even when pedagogically grounded rubrics are applied by experts, results are often summarized using coarse aggregates such as mean rubric scores, percent endorsement by criterion, or composite ratings [37, 46]. These summaries implicitly treat observed ratings as direct measurements of pedagogical effectiveness, which is problematic for at least three reasons. First, human judgments can vary systematically with rater severity or leniency, producing shifts in scores that are unrelated to the chatbot's underlying instructional quality [4, 54]. Second, rubric criteria are rarely equally difficult to satisfy, particularly for tutoring behaviors that require diagnosis and targeted remediation, so aggregation can mask which instructional capabilities are genuinely challenging for the system [31, 40, 38]. Third, many evaluations use cost-constrained annotation designs in which different raters score different subsets of responses, creating partially crossed designs where rater severity can become confounded with the specific responses and query contexts being scored [42]. Together, these limitations motivate a psychometric evaluation layer that can separate response quality from rater effects and criterion difficulty, and support context-conditional interpretation of rubric-based tutoring performance.

These limitations are especially consequential in programming support settings. Pedagogical effectiveness depends not only on producing a fluent response, but on accurately diagnosing student errors (e.g., identifying and localizing mistakes), providing conceptually sound guidance, and offering actionable next steps while respecting constraints that discourage directly revealing solutions. At the same time, the learner's query context strongly conditions what the chatbot can infer and how its response is judged. Students may provide complete code and error traces, partial snippets, or only a high-level description of confusion. Likewise, the requested assistance may range from debugging and error localization to conceptual explanations or strategy-level guidance. Without modeling query sufficiency and question type, it is difficult to determine whether observed rubric scores reflect the chatbot's underlying instructional capability or systematic variation in the interaction context that shapes both response generation and human judgment.

To address these gaps, we propose a Bayesian explanatory Many-Facet Rasch Model (MFRM) as a psychometric evaluation layer for rubric-based assessment of LLM tutoring responses in authentic programming help interactions. Our approach places rubric-criterion endorsements on a common logit scale and separates observed ratings into (i) latent response-level pedagogical quality, (ii) criterion difficulty, and (iii) rater severity, enabling uncertainty-aware inference even under human-annotation designs where rater severity and criterion difficulty would otherwise be confounded in simple aggregates. We further incorporate interaction-context information, most notably whether the student provided sufficient inputs (e.g., code and error traces), as criterion-specific explanatory effects, so that tutoring quality can be interpreted conditional on the help-seeking context rather than as a single global average.

This framework yields criterion-level diagnostics that are not available from raw endorsement rates or standard automated metrics and supports more actionable conclusions about where LLM tutors succeed and where they break down. In this study, we focus on mistake-remediation tutoring behaviors in a C++ debugging task and use a rubric that explicitly distinguishes *mistake location* from mistake identification and isolates *accuracy of guidance* to capture potentially harmful hallucinated or misapplied recommendations. Guided by this evaluation framework, we address the following research questions:

RQ1. Which pedagogical rubric criteria are easiest versus most difficult for an LLM-based programming tutor to satisfy, after accounting for rater severity?

RQ2. How does student-query sufficiency shift the probability that the chatbot satisfies each pedagogical criterion in a programming task?

RQ3. How does student question content relate to criterion-level pedagogical effectiveness in a programming task? *(exploratory)*

We make three contributions. First, we operationalize mistake-remediation tutoring quality for programming support with a rubric and annotation protocol that separates diagnosis (identifying and locating mistakes) from downstream guidance and correctness. Second, we introduce a Bayesian explanatory MFRM that converts rubric-based human judgments into facet-adjusted, uncertainty-aware estimates of pedagogical effectiveness and quantifies how evaluation shifts with query sufficiency. Third, we provide empirical evidence that diagnosis is the limiting capability for the studied tutor and that commonly used reference-free automated metrics capture only a weak proxy for correctness-focused outcomes.

2. RELATED WORK

2.1 LLM Chatbots as Instructional Agents

LLM-based chatbots have emerged in recent years, advancing beyond traditional rule-based algorithms, which have been limited in language understanding. Additionally, responses from rule-based algorithms are planned and predefined [48], which pose challenges regarding unexpected inputs by learners. In contrast, LLM-based chatbots directly address this constraint by training on large-scale datasets, allowing it to capture more contextual and semantic understanding [61], forgoing the need for rigid pre-planning for every potential input. Furthermore, its generative ability to produce natural language supports student learning experiences. Interactions with LLM-based instructional agents are

adaptive, provide timely feedback, and serve as an effective resource for on-demand information [2, 45, 43, 44].

LLM-based chatbots are rapidly reshaping programming education by providing on-demand, natural-language tutoring that can explain concepts, diagnose errors, and support debugging workflows in ways that earlier pre-defined rules or narrowly trained course chatbots struggled to achieve [56]. In authentic course settings, students use LLM tutors for a wide range of needs, but the dominant pattern is highly task-proximal help on assignments (e.g., fixing code, interpreting errors), with comparatively fewer interactions aimed at deeper conceptual inquiry, which raises both opportunity and risk for learning [47]. Recent systems for computing education have introduced instructional guardrails that avoid revealing complete solutions while still offering actionable, context-aware guidance, demonstrating that LLM chatbots can be intentionally shaped toward pedagogically meaningful behaviors [29, 25].

At the same time, evidence from programming courses suggests that students' use of general-purpose chatbots (e.g., ChatGPT) often concentrates on error checking and debugging and may be perceived as helpful for understanding and productivity, yet it can also introduce concerns about code quality, learning, and collaboration practices such as pair programming [18]. Alongside these classroom deployments, research prototypes increasingly combine LLM generation with program-analysis constraints to deliver finer-grained "next-step" hints, aiming to preserve learner agency while improving technical correctness and usefulness [5]. Collectively, this literature motivates treating LLM-based programming tutors not as monolithic tools but as designable instructional systems whose pedagogical value depends on their guardrails, the kinds of help students seek, and the learning context in which they are embedded [25, 47, 18].

2.2 Chatbot Pedagogical Efficacy Evaluation

Approaches to evaluating chatbots vary widely depending on the evaluation goal and the construct of interest. Prior reviews highlight that chatbot evaluation spans multiple perspectives, including user experience, information retrieval, linguistic quality, technical performance, and business outcomes, each emphasizing different attributes and metrics [39]. For instance, linguistic evaluations emphasize response correctness and coherence, whereas user-experience evaluations focus on usability and task completion. Within education, commonly reported objectives include acceptance and adoption, learning outcomes, motivation and affect, usability, technical correctness, and other psychological factors [21]. In this study, we focus specifically on *pedagogical efficacy*, which is define as the extent to which a chatbot supports learning through instructionally appropriate behaviors (e.g., promoting active learning, adapting support to learner needs, managing cognitive load) [24, 31].

Given these objectives, chatbot evaluations are typically conducted through Wizard-of-Oz studies, controlled laboratory experiments, field deployments, or technical validation studies [39]. Measurement within these designs most often relies on human judgments or user-reported instruments (e.g., rubrics, rating scales, surveys), sometimes complemented by behavioral indicators such as task success or learning gains. For example, to operationalize pedagogical ability, Maurya et al. propose eight rubric dimensions rated by human annotators on a 3-point scale [31]. More recently, automated evaluation has also been explored, particularly through lexical-overlap or classification metrics (e.g., BLEU, accuracy, F1, precision/recall) and related reference-based similarity measures (e.g., METEOR, ROUGE, CIDEr), which assume the availability of ground-truth target responses [13, 10, 35]. However, because pedagogical efficacy depends on context-sensitive instructional moves rather than surface similarity to a single reference, these automated metrics are often insufficient on their own, which helps explain why human judgment remains the dominant evidence source for pedagogical evaluation.

Consequently, the empirical literature most often reports effectiveness through aggregated human ratings or rankings. This spans the broader scope of the effectiveness of conversational agents, including educational chatbots. For example, the BEA 2023 shared task evaluated candidate *AI-teacher* responses using 298 crowd raters from Prolific [50], where each interaction was judged by multiple raters and systems were primarily compared via average ranks (1=best to 4=worst) and aggregate leaderboard scores. Similar aggregation based reporting is also common in the broader conversational-systems literature, where small panels of annotators or crowd workers rate responses on a handful of quality dimensions and results are reported as mean or composite scores [22, 16]. For instance, Jiang and Ahuja [22] collected three assessors' judgments per response on informativeness, fluency, and human-likeness and used the mean rating as the primary quality measure. Gao and Jiang [16] similarly recruited crowd workers to rate responses on multiple attributes (e.g., usefulness, accuracy, fluency, human-likeness) and reported performance via aggregated scores across conditions.

More education-focused LLM-tutor evaluations also follow this pattern, but with limited crossing and sparse overlap for reliability estimation. For instance, Daheim et al. [11] annotated a random set of 40 conversations and computed inter-rater reliability using only a small overlapping subset (9 conversations annotated by at least two raters), while still presenting results as criterion-level or overall aggregates. Even when evaluation is framed as comparative judgment, the reporting often remains rank- or mean-based. A few studies proposed to use pairwise comparative judgments and a probabilistic ranking model to infer pedagogical ability, yielding system-level scores and rankings rather than rater- and criterion-adjusted measures [51]. Collectively, this literature provides clear evidence that (a) evaluation commonly depends on human labels collected under partial crossing (different raters score different subsets), (b) outcomes are typically communicated as means, ranks, or composites, and (c) rater disagreement is acknowledged via inter-rater reliability but rarely incorporated into the final scoring model, thus, motivating measurement-model-based approaches that explicitly separate latent pedagogical quality from rater severity and criterion difficulty.

2.3 Bayesian explanatory MFRM

The LLM-based chatbot response to a student's single query is identified as a pair of *Chatbot response* and *student query*

that are rated by multiple raters. A Bayesian explanatory many-facet Rasch model (MFRM) is a Rasch-family model that decomposes the score or rating into multiple additive facets on a common logit scale. These typically involve criterion or item difficulty, response quality, and rater severity, while also allowing other covariates to explain systematic variation in ratings. This study showcases a novel application of MFRM by allowing the quality of chatbot's response as an evaluation target, and introducing other critical covariates that can systematically influence pedagogical quality.

Specifically, let $i \in \{1, \ldots, I\}$ index student–chatbot exchanges (responses), $j \in \{1, \ldots, J\}$ index rubric criteria, and $r \in \{1, \ldots, R\}$ index human raters. Let $y_{ijr} \in \{0, 1\}$ denote a binary endorsement indicating whether rater r judged response i as satisfying criterion j (1=endorsed, 0=not endorsed). We analyze the data in long format and index each observed rating by $n \in \{1, \ldots, N\}$ with mappings $i(n)$, $j(n)$, and $r(n)$. The model decomposes endorsements into (i) response-level latent pedagogical quality θ_i (higher values imply higher endorsement probability across criteria), (ii) criterion difficulty b_j (larger values indicate harder-to-satisfy criteria), and (iii) rater severity s_r (larger values indicate stricter raters, reducing endorsement probability), while allowing criterion-specific effects of query context covariates.

$$y_n \mid p_n \sim \text{Bernoulli}(p_n), \qquad \text{logit}(p_n) = \eta_n,$$
$$\eta_n \;=\; \theta_{i(n)} - b_{j(n)} - s_{r(n)} \;+\; \gamma_{j(n)} v_n \;+\; \sum_{k=1}^{K} \beta_{j(n)k}\, x_{nk}. \tag{1}$$

To characterize how the help-seeking context conditions rubric endorsement, we included two sets of query-level covariates. First, *input sufficiency* was encoded as a binary indicator $v_n \in \{0, 1\}$, where $v_n = 1$ denotes that the student query provided sufficient information (e.g., code, error traces, and/or descriptive context) for a meaningful diagnosis and response.[1] Second, we represented the *CS topic content* of each student query using K multi-label binary indicators $\{x_{nk}\}_{k=1}^{K}$, where $x_{nk} = 1$ if topic k is present in the query and $x_{nk} = 0$ otherwise (multiple topics may be active for the same query). Under this specification, γ_j captures the criterion-specific shift in endorsement associated with sufficient inputs, and β_{jk} captures the criterion-specific association between topic k and endorsement.

Because the logistic Rasch family is location-invariant, we imposed sum-to-zero constraints on additive facets via centering. Operationally, we sampled unconstrained raw parameters and applied mean-centering transformations: $\theta_i = \theta_i^{\text{raw}} - \overline{\theta^{\text{raw}}}$ and $s_r = s_r^{\text{raw}} - \overline{s^{\text{raw}}}$. For the topic coefficients, we imposed a within-criterion sum-to-zero constraint across the K topic effects, $\sum_{k=1}^{K} \beta_{jk} = 0$ for each criterion j, implemented as $\beta_{jk} = \beta_{jk}^{\text{raw}} - \overline{\beta_{j\cdot}^{\text{raw}}}$, where $\overline{\beta_{j\cdot}^{\text{raw}}} = \frac{1}{K}\sum_{k=1}^{K} \beta_{jk}^{\text{raw}}$. This constraint is compatible with multi-label topic coding because it centers the criterion-specific topic coefficients, not the observations.

[1]If input sufficiency was coded separately by each rater, then v_n is indexed by the rater in observation n; otherwise, v_n is treated as an exchange-level label shared across ratings for the exchange.

We used weakly informative Normal priors: θ_i^{raw}, b_j, $s_r^{\text{raw}} \sim \mathcal{N}(0, 1)$ and γ_j, $\beta_{jk}^{\text{raw}} \sim \mathcal{N}(0, 0.5^2)$. Posterior inference targeted $p(\boldsymbol{\Theta}, \mathbf{b}, \mathbf{s}, \boldsymbol{\gamma}, \mathbf{B} \mid \mathbf{y})$, where $\boldsymbol{\Theta} = \{\theta_i\}_{i=1}^{I}$, $\mathbf{b} = \{b_j\}_{j=1}^{J}$, $\mathbf{s} = \{s_r\}_{r=1}^{R}$, $\boldsymbol{\gamma} = \{\gamma_j\}_{j=1}^{J}$, and $\mathbf{B} = \{\beta_{jk}\}_{j=1,k=1}^{J,K}$.

$$p(\boldsymbol{\Theta}, \mathbf{b}, \mathbf{s}, \boldsymbol{\gamma}, \mathbf{B} \mid \mathbf{y}) \propto \prod_{n=1}^{N} \text{Bernoulli}\big(y_n \mid \text{logit}^{-1}(\eta_n)\big) \times p(\boldsymbol{\Theta})\, p(\mathbf{b})\, p(\mathbf{s})\, p(\boldsymbol{\gamma})\, p(\mathbf{B}). \tag{2}$$

We used Hamiltonian Monte Carlo with the No-U-Turn Sampler (NUTS), running 4 chains with 1,000 warmup iterations and 1,000 retained posterior draws per chain. Convergence was assessed using $\hat{R}$ and effective sample size.

For interpretable effect sizes, we translated selected effects into probability changes as the coefficients were estimated on the log-odds scale. For instance, for input sufficiency effect, for each rubric criteria j, we defined a baseline linear predictor at a reference point $\theta^*, s^*, \mathbf{x}^* = 0$ as follows:

$$\eta_{0j} = \theta^* - b_j - s^* \tag{3}$$

Then, the probability shift induced by input sufficiency is expressed as follows, where $\Delta P_j^{(suff)}$ was computed for each posterior draw to obtain a posterior distribution over probability-scale effects, summarized by posterior mean and 94% HDI.

$$\Delta P_j^{(suff)} = \sigma(\eta_{0j} + \gamma_j) - \sigma(\eta_{0j}), \quad \sigma(t) = \frac{1}{1 + e^{-t}} \tag{4}$$

3. METHODS

3.1 Participants and Data Collection

This study was conducted in a large-enrollment undergraduate computer science course at a public, research-intensive university in the southern United States (Spring 2024; $N = 669$)[2]. The course emphasized object-oriented programming in C++, and students could voluntarily use CodeHelp [29], which is an LLM-based programming tutor designed to provide debugging-oriented guidance while discouraging solution revealing, during a course assignment. We analyzed 249 unique, single-turn student-chatbot exchanges (one per student), each pairing a student query (including any provided code/error context captured by the platform) with the corresponding chatbot response. We excluded attempted submissions that CodeHelp flagged as insufficient and for which no response was returned.

3.2 Programming Task and Interaction Inputs

Students completed a C++ programming task targeting an intermediate object-oriented programming concept commonly referred to as the "Big Three" implementation (Fig. 4). The task required implementing a destructor, copy constructor,

[2]This study was conducted in accordance with institutional ethical guidelines for research involving human participants. The research protocol was reviewed and approved by the Institutional Review Board (IRB) RB202400344. All data involving human participants were handled in compliance with relevant privacy and ethical standards.

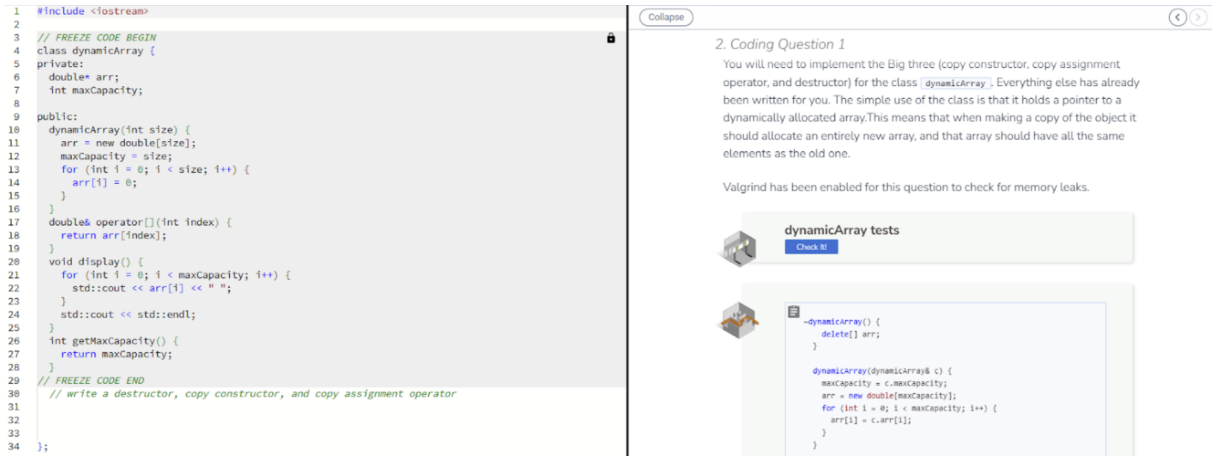

Figure 1: Programming Task Description

and copy assignment operator for a class that manages dynamically allocated memory and resources. The programming environment integrated Valgrind to detect runtime memory errors and memory leaks to support debugging. When interacting with CodeHelp, students could provide information via one or more fields: (1) *Code* (a snippet of their implementation), (2) *Error* (compiler output or Valgrind messages), and (3) *User Input* (a natural-language description of the issue). For each exchange, we logged the contents of these fields and the chatbot response.

3.3 Chatbot Evaluation

3.3.1 Rubric Development and Query Labels

To evaluate the pedagogical quality of chatbot responses in a mistake-remediation programming context, we adapted the unifying framework for mistake-remediation tasks [31, 24, 38]. The framework emphasizes core dimensions of tutoring quality (e.g., mistake remediation and guidance/actionability). Because our task required assessing whether the chatbot could pinpoint where an error occurred in student code, we introduced a dedicated *Mistake Location* dimension. To distinguish helpful guidance from potentially harmful or hallucinated recommendations, we additionally included an *Accuracy of Guidance* dimension. Table 1 summarizes all rubric dimensions. Detailed decision rules and benchmark examples used in annotator training are provided in Appendix A.

For modeling, we used a binary endorsement format. For dimensions i1–i4, raters initially assigned *yes/partial/no*, and we recoded *partial* as *no* (i.e., Yes= 1, Partial/No= 0). In this study, we treated partial as not-fully-met to target a conservative mastery-like endorsement. Dimension i5 was coded as Yes/No. In addition to rubric-based response-quality criteria, raters also coded two auxiliary query-level labels: *Input Sufficiency* (S; whether the student provided enough information for a meaningful response) and *CS topic categories* describing the content of the student query. Topic codes were multi-label (a single exchange could receive multiple topic categories). Table 2 summarizes the distribution of topic labels across exchanges.

3.3.2 Annotator Training and Coding Procedure

Table 1: Rubric Dimensions for Chatbot Evaluation

ID	Dimension	Scale	Description
Rubric dimensions (chatbot response quality)			
i1	Mistake Identification	yes partial no	Does the chatbot accurately recognize a mistake in the student's input?
i2	Mistake Location	yes partial no	Does the chatbot correctly identify the location/aspect of the student's mistake?
i3	Providing Guidance	yes partial no	Does the chatbot offer guidance relevant to the identified issue?
i4	Accuracy of Guidance	yes partial no	Is the guidance factually and conceptually correct?
i5	Correctness of Next Step	yes no	Are the suggested next steps and corrections accurate and appropriate?
Auxiliary query-level labels			
S	Input Sufficiency	yes no	Did the student provide enough information (e.g., code, error, context) for a meaningful response?

Table 2: Student Queries by Relevant CS Topics (multi-label)

Category	Description	Freq
Topic 1	Programming Fundamentals	146
Topic 2	Data Management and Processing	130
Topic 3	Object-Oriented Programming (OOP)	176
Topic 4	Code Construction	216
Topic 5	Language Unique Programming Concepts	239

Two subject matter experts independently coded all 249 student–chatbot exchanges. Before full coding, raters reviewed the task description, rubric definitions, and benchmark examples, and completed a structured training session to align decision rules. Raters then double-coded a random set of 20 exchanges and participated in a calibration meeting to resolve ambiguities and refine guidelines. A midpoint check-in was conducted to reinforce decision rules and ensure continued consistency. Disputed training cases were resolved by consensus and incorporated into an updated benchmark set used for ongoing reference during coding. Unless otherwise noted, analyses used both raters' original codes to estimate and adjust for rater severity within the many-facet Rasch framework.

Table 3: Model comparison using PSIS-LOO

Model	elpd_{loo}	SE	Δelpd	p_{loo}	Wt.	Rank
$M1_{\text{suff}}$	-1419.00	22.23	2.45	135.55	1.00	0
$M0_{\text{baseline}}$	-1421.45	22.18	0.00	135.20	0.00	1
$M3_{\text{both}}$	-1428.32	22.72	-6.87	153.87	0.00	2
$M2_{\text{topics}}$	-1430.19	22.69	-8.74	153.42	0.00	3

Note. Higher elpd_{loo} indicates better expected out-of-sample predictive fit. Δelpd is relative to $M0_{\text{baseline}}$.

Table 4: Observed endorsement rates by raters

Rater	i1	i2	i3	i4	i5
Rater 1	0.530	0.542	0.406	0.892	0.827
Rater 2	0.510	0.482	0.394	0.880	0.867

4. RESULTS

All models were fit to a long-format dataset with $N = 2{,}490$ binary observations (249 exchanges $\times$ 5 rubric criteria $\times$ 2 raters). Submissions flagged by our LLM-based chatbot, CodeHelp, as insufficient were excluded prior to annotation because no response was returned in such cases; SMEs labeled 5% as insufficient on the Input Sufficiency label (S). For modeling, *partial* ratings were recoded as 0 (not endorsed) to yield binary endorsements..

We evaluated out-of-sample predictive performance using PSIS-LOO computed from 4,000 posterior draws and the pointwise log-likelihood matrix. For the facets-only baseline model ($M0_{\text{baseline}}$), PSIS-LOO indicated stable importance sampling with all Pareto-k values ≤ 0.70 (100% "good"). We then compared four nested specifications (Table 3): a facets-only baseline ($M0_{\text{baseline}}$), a primary explanatory model adding criterion-specific input-sufficiency effects ($M1_{\text{suff}}$), and extended models that additionally included multi-label topic indicators ($M2_{\text{topics}}$) or both covariate sets ($M3_{\text{both}}$). Adding input sufficiency produced a small improvement in expected out-of-sample fit relative to the baseline ($\Delta\text{elpd}_{\text{loo}} = +2.45$), whereas including topic indicators increased effective model complexity ($p_{\text{loo}} \approx 153$) without improving PSIS-LOO, where $\Delta\text{elpd}_{\text{loo}} < 0$ for $M2_{\text{topics}}$ and $M3_{\text{both}}$. Accordingly, we use $M1_{\text{suff}}$ as the primary model for inference in RQ1–RQ2 (criterion difficulty and input sufficiency effects) and treat topic-based analyses (RQ3) as exploratory. We summarize posterior uncertainty using 94% highest-density intervals (HDIs).

Across the 249 exchanges, the two raters showed broadly similar endorsement patterns across criteria (Table 4). Here, we use *endorsement* to denote cases in which a criterion was judged as met (i.e., rated `yes`; see rubric in Table 1). Both raters endorsed the chatbot most frequently on Accuracy of Guidance (i4) and correctness of next steps (i5), and least frequently on Providing Guidance (i3), with intermediate endorsement for mistake identification and localization (i1–i2). This suggests that the chatbot more often produced factually correct and actionable guidance once it engaged with the problem, but struggled more consistently with diagnosing and responding to the student's specific error.

Table 5: Posterior mean rater severity estimates

Rater	$\bar{s}_r$
Rater 1	-0.036
Rater 2	$+0.036$

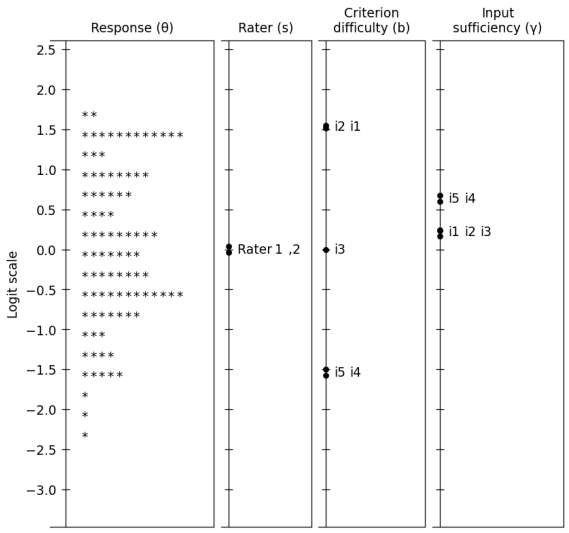

Figure 2: Posterior parameter map for the primary MFRM model ($M1_{\text{suff}}$).

We then fit a Bayesian explanatory Many-Facet Rasch Model (MFRM) to disentangle rater severity, criterion difficulty, and response-level pedagogical quality. Posterior mean rater severities were near zero and symmetric ($s_{\text{rater1}} = -0.036$, $s_{\text{rater2}} = +0.036$), indicating minimal systematic differences in endorsement tendency after accounting for criterion difficulty and response quality (Table 5). Response-level pedagogical quality estimates (θ_i; $I = 249$) were centered near zero by model identification ($\bar{\theta} \approx 0$, $SD \approx 1$) and spanned a broad range (min $= -2.45$, max $= 1.60$), indicating substantial heterogeneity in the chatbot's pedagogical effectiveness across student queries and underscoring the need to model response quality beyond raw aggregate endorsement rates.

4.1 Rubric criterion difficulty (RQ1)

Using the primary model $M1_{\text{suff}}$ (facets + input sufficiency), criterion difficulty estimates (b_j) indicated substantial differences in how challenging each pedagogical criterion was for the chatbot to satisfy. Larger b_j corresponds to a lower probability of endorsement, holding response quality and rater severity constant. The mistake diagnosis criteria were most difficult: Mistake Identification (i1) and Mistake Location (i2) had the largest positive posterior mean difficulties ($\bar{b}_{i1} = 1.517$, $\bar{b}_{i2} = 1.553$). Providing Guidance (i3) was close to the reference point ($\bar{b}_{i3} \approx 0$). In contrast, the accuracy-oriented criteria were easiest: Accuracy of Guidance (i4) and Correctness of next steps (i5) had negative difficulty estimates ($\bar{b}_{i4} = -1.577$, $\bar{b}_{i5} = -1.493$), indicating these behaviors were endorsed more readily. For interpretability, we also report baseline endorsement probabilities at a common reference setting ($\theta = 0$, $s = 0$, and $v = 0$). Baseline endorsement was lowest for i1 (0.188) and i2 (0.183), moderate for i3 (0.500), and high for i4 (0.819) and i5 (0.807) (Table 6). Together, these results suggest that the primary difficulty for the chatbot lies in *diagnosing* and *localizing* student errors, rather than in producing generally accurate or actionable guidance once an issue is addressed.

Table 6: Rubric criterion difficulty and baseline endorsement probability at the reference point

ID	Criterion	$\bar{b}_j$	94% HDI	$\bar{p}_{\text{base}}$	94% HDI
i1	Mistake identification	1.517	[0.820, 2.451]	0.188	[0.079, 0.306]
i2	Mistake location	1.553	[0.835, 2.516]	0.183	[0.075, 0.303]
i3	Providing guidance	-0.000	[-0.773, 0.768]	0.500	[0.317, 0.684]
i4	Accuracy of guidance	-1.577	[-2.666, -0.812]	0.819	[0.693, 0.935]
i5	correctness of next steps	-1.493	[-2.481, -0.724]	0.807	[0.674, 0.923]

Table 7: Input sufficiency effects by criterion.

ID	$\bar{\gamma}_j$	94% HDI	$\bar{p}_{\text{base}}$	$\overline{\Delta P}$	94% HDI
i1	0.242	[-0.384, 0.908]	0.188	0.037	[-0.067, 0.143]
i2	0.237	[-0.403, 0.871]	0.183	0.035	[-0.069, 0.135]
i3	0.169	[-0.451, 0.867]	0.500	0.041	[-0.109, 0.209]
i4	0.596	[-0.107, 1.278]	0.819	0.072	[-0.015, 0.169]
i5	0.672	[-0.007, 1.371]	0.807	0.083	[-0.008, 0.188]

Note. ΔP summarizes the probability change induced by sufficiency at the reference point ($\theta = 0$, $s = 0$, covariates $= 0$).

4.2 Effects of input sufficiency (RQ2)

Using the primary model $M1_{\text{suff}}$ (facets + input sufficiency), we examined whether rater-judged input sufficiency (i.e., whether the student query contained enough information to diagnose and address the issue) was associated with higher endorsement probabilities via criterion-specific effects (γ_j). Posterior mean sufficiency effects were positive across all criteria (Table 7), with larger mean shifts for the accuracy-oriented criteria (i4, i5). On the probability scale, the estimated mean changes were modest for the diagnosis and guidance criteria ($\Delta P \approx 0.037$–0.041 for i1–i3) and larger for the accuracy-oriented criteria ($\Delta P \approx 0.072$–0.083 for i4–i5). However, the 94% HDIs indicate substantial uncertainty, consistent with the small proportion of exchanges labeled as insufficient (5%) in the current dataset.

Figure 2 visualizes posterior parameter estimates from $M1_{\text{suff}}$, with all panels plotted on a common logit scale for comparison. The response-quality distribution (θ, left) shows substantial heterogeneity across student–chatbot exchanges. Rater severity estimates (s, second) are centered near zero for both raters, indicating minimal systematic differences in endorsement tendency. Criterion difficulty (b, third) differentiates the rubric criteria, with mistake diagnosis (i1–i2) the most difficult and the accuracy-oriented criteria (i4–i5) the easiest. Finally, the input-sufficiency effects (γ, right) are generally positive but imprecisely estimated, suggesting that more sufficient student queries may increase endorsement probabilities, with the largest expected gains for the accuracy-related criteria.

4.3 Exploratory Analysis for Effects of student query topic (RQ3)

We conducted an exploratory analysis of whether student question content was associated with criterion-level rubric outcomes. Specifically, we used multi-label indicators for five CS topic categories (Table 2) to summarize topic-conditional differences in endorsement and to estimate topic-augmented MFRM specifications (Figure 3; Table 8). Because adding topic indicators did not improve PSIS-LOO relative to the primary model and increased effective complexity (Table 3), we interpret topic patterns as descriptive and hypothesis-generating rather than confirmatory effects.

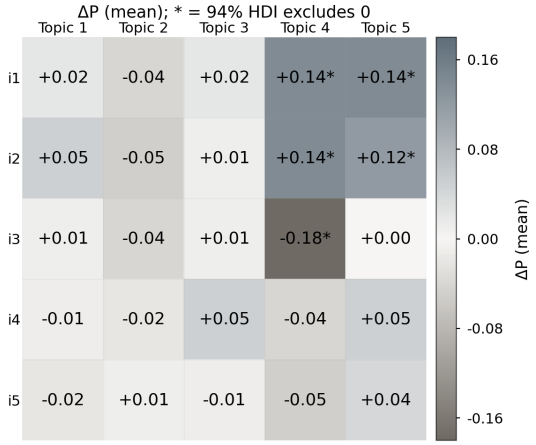

Figure 3: Topic effects by rubric criterion

Overall, topic-related variation was most apparent for the diagnosis-related criteria, Mistake Identification (i1) and Mistake Location (i2), and for Providing Guidance (i3). In contrast, topic associations for the accuracy-oriented criteria (i4–i5) were smaller and more uncertain, with 94% HDIs often spanning zero. In the topic-augmented model, topic effects are summarized as posterior mean probability shifts (ΔP) at a common reference point ($\theta = 0$, $s = 0$, input sufficiency $v = 0$, and other topic indicators set to 0), enabling criterion-by-topic comparisons on the probability scale.

For mistake diagnosis, the largest positive associations were observed for *Code Construction* (Topic 4) and *Language-Unique Programming Concepts* (Topic 5). For i1, Topic 4 and Topic 5 were associated with increases of approximately $\Delta P \approx +0.14$, with 94% HDIs excluding zero; a similar

Table 8: Exploratory topic associations with criterion endorsement (topic-augmented model).

i5	5	0.292	[-0.427, 1.039]	0.041	[-0.066, 0.151]						

Note. Each row reports the criterion–topic effect $\beta_{j,k}$ and the corresponding probability shift ΔP at the reference point ($\theta = 0$, $s = 0$, and other topic indicators set to 0). 94% HDIs are computed from the posterior.

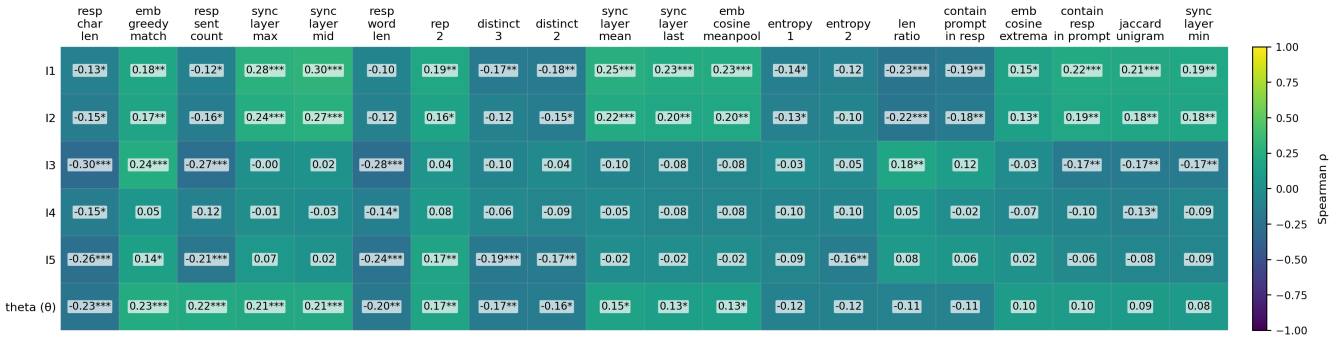

Figure 4: Spearman's correlations between the evaluation metrics and target rubric

pattern emerged for i2 (Topic 4: $\Delta P \approx +0.14$; Topic 5: $\Delta P \approx +0.12$). By comparison, *Programming Fundamentals* (Topic 1), *Data Management and Processing* (Topic 2), and *Object-Oriented Programming* (Topic 3) showed smaller shifts for i1 and i2 (typically $|\Delta P| \leq 0.05$) with uncertainty intervals overlapping zero.

Providing Guidance (i3) exhibited an asymmetric pattern: most topics were near zero, whereas *Code Construction* (Topic 4) was associated with a notable decrease in endorsement ($\Delta P \approx -0.18$; 94% HDI excluding zero). Taken together, this pattern suggests that topic differences may be most consequential for upstream diagnosis and for translating diagnosis into actionable guidance. However, given the lack of PSIS-LOO improvement for topic-augmented models, these results should be interpreted cautiously and motivate future work with larger or more balanced samples to test topic moderation more decisively.

4.4 Comparisons to Automated Metrics

To contextualize our rubric-based evaluation and provide convergent and discriminant validity evidence for the pedagogical constructs targeted by i1–i5, we compared rubric outcomes against a set of automated, reference-free metrics computed from each student–chatbot exchange. These included (a) *surface length and structure* (response character length, word length, sentence count, and the response-to-prompt length ratio), (b) *lexical diversity and redundancy* (type–token ratio; distinct-n for $n \in 1, 2, 3$; normalized n-gram entropy for $n \in 1, 2$; and repetition rates for unigram and bigram reuse), (c) *prompt–response overlap* (unigram and bigram Jaccard overlap; prompt containment in the response and vice versa), and (d) *readability* (Flesch Reading Ease and Flesch–Kincaid Grade). To approximate semantic relatedness without an external reference, we additionally computed *embedding-based similarity* between the prompt and response (mean-pooled cosine similarity, vector-extrema cosine similarity, and greedy token-level matching) and *layerwise synchrony* scores, defined as the cosine similarity between mean-pooled transformer representations across layers and summarized by the minimum, mean, maximum, mid-layer, and last-layer similarity. For each metric, we computed Spearman rank correlations (ρ) with (a) criterion-level endorsements (i1–i5) and (b) the response-level latent pedagogical quality estimate (θ) from the MFRM, and we summarize the correlation pattern in Figure 4. These correlations provide convergent evidence when rubric scores align with the signal captured by a specific class of metrics.

Overall, the correlation coefficients between automated metrics and rubric-based outcomes were generally modest (typically $|\rho| \leq .30$), indicating that commonly used reference-free metrics capture only partial information about pedagogical response quality. The MFRM latent quality estimate

θ aligned most consistently with semantic relatedness between the student query and the chatbot response, including embedding-based relevance (greedy matching; $\rho = .23^{***}$) and synchrony-based similarity (sync layer max and mid; $\rho = .21^{***}$), with smaller positive associations for overlap and reuse proxies (rep-2; $\rho = .17^{**}$). In contrast, θ was negatively associated with verbosity and lexical diversity indicators, including response length ($\rho \approx -.20$ to $-.23$) and distinctness measures (distinct-2/3; $\rho \approx -.16$ to $-.17$). Together, these findings suggest that higher-quality chatbot responses, as captured by θ, tend to be more directly aligned with the student prompt and more concise, rather than longer or more lexically diverse.

At the rubric-criterion level, the clearest alignment with automated metrics emerged for the chatbot's *diagnosis* behaviors. Mistake Identification (i1) and Mistake Location (i2) were positively associated with prompt-response semantic relatedness, including synchrony-based similarity (sync layer max and mid; i1 $\rho = .28^{***}$ and $.30^{***}$; i2 $\rho = .24^{***}$ and $.27^{***}$) and lexical overlap (unigram Jaccard; i1 $\rho = .21^{***}$; i2 $\rho = .18^{**}$). Both criteria were also negatively related to indicators of disproportionate or overly expansive responses, including the response-to-prompt length ratio (len ratio; i1 $\rho = -.23^{***}$; i2 $\rho = -.22^{***}$) and prompt-containment features (contain prompt in response; i1 $\rho = -.19^{**}$; i2 $\rho = -.18^{**}$), suggesting that higher diagnostic ratings tended to occur when responses stayed targeted to the student's query. Providing Guidance (i3) showed a different pattern that is related to a more concise and actionable help. Guidance endorsements were strongly negatively associated with verbosity (response character length $\rho = -.30^{***}$; sentence count $\rho = -.27^{***}$; word length $\rho = -.28^{***}$) while remaining positively related to embedding-based relevance (greedy matching; $\rho = .24^{***}$). This profile is consistent with raters rewarding guidance that is directly responsive and succinct rather than lengthy or diffuse.

In contrast, the correctness-focused criteria exhibited the weakest convergence with the automated metrics. Accuracy of Guidance (i4) showed near-zero correlations across most measures (with only small negative relationships with response length), and Correctness of next steps (i5) was primarily associated with surface length and diversity proxies rather than stronger positive semantic alignment signals. Overall, these findings indicate that standard reference-free features predominantly capture relevance and alignment and surface form (verbosity and lexical diversity), but provide incomplete coverage of pedagogically consequential constructs, particularly factual or conceptual correctness and the appropriateness of next-step suggestions. This limitation motivates the use of expert rubric scoring and psychometric modeling for rigorous evaluation of educational chatbot responses.

5. DISCUSSION

This study introduces a Bayesian explanatory Many-Facet Rasch Model (MFRM) as a psychometric evaluation layer for rubric-based assessment of LLM tutoring responses in authentic programming help interactions. Instead of interpreting rubric endorsements as direct measures of pedagogical effectiveness, the model disentangles latent response quality from rubric-criterion difficulty and rater severity, and incorporates interaction context through query-level covariates. The resulting facet-adjusted estimates provide a more diagnostic and context-sensitive characterization of tutoring performance than raw means or endorsement rates, clarifying when our LLM-based chatbot performs well and where it breaks down across pedagogically meaningful dimensions.

Our work builds on a small but growing set of Rasch-family applications to LLM and chatbot evaluation, which largely follow two patterns. One line of work treats a chatbot as an "examinee" and applies Rasch analysis to place chatbots and test items on a common proficiency scale, often using domain testing formats such as medical or STEM multiple-choice benchmarks [6]. While useful for benchmarking performance relative to item difficulty, this approach typically focuses on correctness in fixed-response tasks and does not directly address human rater-mediated judgments of open-ended tutoring quality. A second line of work uses many-facet Rasch models in rating systems, particularly when an LLM functions as an automated scorer or rater, with the primary goal of quantifying severity, fit, and bias relative to human raters [60, 23, 26]. Related work extends MFRM to broader human-evaluation pipelines for AI-generated conversations by jointly modeling rater effects and contextual facets [34]. Our contribution is distinct from both benchmark scaling and rater auditing alone. We operationalize MFRM for rubric-scored, open-ended tutoring behaviors under authentic help-seeking conditions and provide a principled procedure for determining which contextual extensions add predictive value. In our data, PSIS-LOO comparisons favored a parsimonious explanatory specification that adds input sufficiency to the core facets, while topic-augmented models increased effective complexity without improving predictive fit (Table 3). This positions the MFRM not only as a scoring model, but as a validity-oriented evaluation layer that supports model checking, uncertainty quantification, and context-conditional interpretation.

Addressing RQ1, criterion difficulty results indicate that the chatbot's pedagogical strengths and weaknesses were not uniformly distributed across tutoring behaviors. Mistake diagnosis criteria, including Mistake Identification (i1) and Mistake Location (i2), were substantially more difficult to satisfy than correctness-oriented criteria, Accuracy of Guidance (i4) and Correctness of next steps (i5). Pedagogically, this pattern suggests that the system more reliably produces technically plausible guidance once it commits to a direction, but is less consistent in upstream tutoring behaviors that require diagnosing what the student did wrong and where the error originates. This asymmetry matters in programming help contexts because effective support typically depends on diagnosis before explanation [58]. Without correctly recognizing and localizing the mistake, fluent and confident guidance can be misaligned with the student's actual issue. From an evaluation standpoint, these findings also clarify why global aggregates can be misleading. If criteria differ substantially in difficulty, collapsing across rubric dimensions can hide critical weaknesses. For example, high endorsement for correctness-oriented criteria can coexist with systematic fragility in diagnosis. The Rasch framing makes this visible by placing criteria on a common logit scale and treating difficulty differences as interpretable measurement parameters [30, 52].

The estimated rater severity parameters were small and symmetric around zero, indicating minimal systematic rater bias after accounting for response quality and criterion difficulty. This is encouraging for rubric-based evaluation because it suggests that conclusions about criterion ordering and response-quality ranking are not driven by one rater being consistently more lenient or severe. At the same time, Cohen's κ was low-to-moderate across dimensions while exact-match agreement was comparatively high. This divergence is consistent with the κ paradox under endorsement imbalance, where high observed agreement can coexist with depressed chance-corrected agreement [15, 9]. In this setting, the MFRM approach is particularly useful because it does not assume perfect agreement. Instead, it uses both raters' codes to estimate and adjust for severity on the same latent scale and propagates uncertainty into criterion-level and response-level estimates.

Addressing RQ2, input sufficiency effects were positive across criteria, with larger posterior mean shifts for the accuracy-oriented criteria (i4–i5). Conceptually, this direction is expected. Richer student context, such as code, error traces, and clear problem statements, should increase the probability that the chatbot can respond appropriately and that raters can evaluate the response favorably. Although uncertainty around these effects remained nontrivial, likely because only a small fraction of retained exchanges were labeled insufficient (about 5%), the PSIS-LOO comparison provided modest evidence that adding sufficiency improves predictive adequacy relative to a facets-only baseline (Table 3). This yields a practical implication for evaluation design. To estimate sufficiency effects more precisely, future datasets may require higher prevalence of insufficient queries or sampling strategies that deliberately balance sufficient and insufficient contexts. More broadly, these results support a context-conditional view of tutoring effectiveness. Observed quality reflects both system capability and what students provide, and a psychometric evaluation layer that conditions on query quality helps separate these components and makes evaluation conclusions more transportable across settings with different help-seeking behavior distributions.

Addressing RQ3, we explored whether question content was associated with criterion-level endorsements using multi-label topic indicators. Topic-conditional patterns suggested that some categories were associated with higher endorsement for diagnosis behaviors, while at least one category was associated with lower endorsement for providing guidance. However, topic-augmented specifications did not improve PSIS-LOO and increased effective complexity, so these findings are best interpreted as descriptive and hypothesis-generating rather than as confirmatory moderation effects (Table 3). Even so, they point to a practical consideration for computing education and LLM tutoring. The same system can appear effective for some help-seeking contexts and less effective for others, and reporting criterion-level outcomes helps make this heterogeneity visible without collapsing everything into a single global score. Future work with larger samples or targeted designs can more decisively test topic moderation and evaluate whether structured interfaces can shift students toward contexts where the tutor behaves more reliably.

The comparison to automated metrics is best interpreted as construct coverage evidence rather than a competition for a single "best" score. We observed only modest alignment between common reference-free metrics and rubric targets, and the correlation structure differed by rubric dimension. In particular, automated metrics captured limited signal for correctness-focused criteria, suggesting that surface form, overlap, and prompt-response relatedness measures do not reliably recover pedagogically consequential judgments about factual correctness and appropriateness of next steps. Taken together, these findings motivate the continued role of expert rubric-based evaluation in educational settings and clarify where automated evaluation may complement, but not replace, pedagogical scoring.

Overall, our results support a context-sensitive interpretation of educational LLM-based chatbot effectiveness. Pedagogical quality depends on what the system can do, what students provide, and which instructional behaviors are being evaluated. By combining expert rubric judgments with a Bayesian explanatory MFRM and explicitly validating model extensions with PSIS-LOO, the proposed approach offers a principled path toward uncertainty-aware, diagnostically meaningful evaluation of LLM-based tutors in authentic learning settings.

6. CONCLUSION AND LIMITATIONS

Several limitations should be considered when interpreting the findings. First, the study examined a single course context, a single programming task (the "Big Three"), and a single tutoring system configuration; generalization to other topics, courses, or tutor designs requires additional evidence. Second, the analysis focused on single-turn exchanges. Multi-turn tutoring introduces additional facets, such as dialogue history, repair trajectories, and evolving student understanding, which may change both rubric constructs and model structure. Future evaluations may benefit from rubric refinements or sampling strategies that ensure adequate variability across criteria. Finally, input sufficiency was relatively rare within the retained sample (5%), which limits precision for estimating sufficiency effects and suggests the need for intentional sampling or larger datasets to more sharply quantify context effects.

This work suggests several directions for improving both evaluation practice and tutoring design. For evaluation, future studies can extend the framework to (i) ordinal scoring (rather than binary endorsement), (ii) additional facets such as rubric-dimension severity differences by rater, and (iii) multilevel structures that account for student-level or prompt-level clustering. For tutor design, the strongest need indicated by criterion difficulty is improved mistake diagnosis: systems may benefit from structured prompting that elicits minimal reproducible examples, explicit error traces, or targeted clarifying questions. Finally, because effectiveness varies by question type, future work should explore adaptive interfaces that guide students toward higher information queries and monitor when the tutor is operating outside its reliable regimes.

APPENDIX
A. DETAILED EVALUATION RUBRIC

i1: Mistake Identification

Guiding Question: *Did the response correctly identify or recognize a mistake in the student's original response?*

This category assesses whether the chatbot response explicitly or implicitly acknowledges **all** errors in the student's answer. Recognition can be **direct** (e.g., pointing out what is incorrect) or **indirect** (e.g., offering a correction or prompting the student to revisit a specific part). When multiple errors are present, it is expected to recognize **each** of them.

- **Yes:** The response correctly identifies all mistakes present in the context, evaluating both the issue and the code.
- **Partially:** The response identifies some mistakes but misses others, or identifies them incompletely.
- **No:** The response fails to identify any mistakes, or incorrectly labels correct elements as mistakes.

Rater Tip: Focus on whether the response shows awareness of the student's mistake, not on how thorough the explanation is or whether the correction is accurate.

i2: Mistake Location

Guiding Question: *Did the response accurately point to a genuine mistake and its location?*

This category assesses whether the chatbot correctly indicates where each identified mistake occurs. For **each** error it recognizes, it should clearly and correctly indicate the relevant portion of the response. Line numbers are not required if the referenced location is unambiguous.

- **Yes:** The response accurately pinpoints the location of all identified mistakes.
- **Partially:** The response locates some, but not all, mistakes. If the response does not explicitly cite a line number but the intended location is clear (e.g., "in the copy assignment operator"), count this as partial.
- **No:** The response fails to locate the mistakes or points to incorrect or nonexistent locations.

Rater Tip: For each mistake identified, check whether the chatbot points to the corresponding location with enough specificity for a student to find it. If the response misses mistakes or misidentifies them, this category should generally be rated **Partially** or **No**.

i3: Providing Guidance

Guiding Question: *Does the chatbot offer guidance that is relevant and responsive to the student's issue?*

This category assesses whether the chatbot offers guidance, such as explanations, elaborations, tips, hints, and examples, that is both relevant and responsive to the issues provided and identified in the context. Fully appropriate guidance clearly addresses the issue without introducing unrelated information, omitting the student's request, or becoming overly generic, taliored to the students' needs.

- **Yes:** The response directly addresses the student's question(s) in context and provides guidance that helps remediate the identified mistake(s).
- **Partially:** The response provides incomplete guidance or includes distracting, tangential information that adds unnecessary cognitive burden.
- **No:** The response provides no guidance or guidance that is largely irrelevant to the student's issue.

Rater Tip: If the response misses part of the question or provides an irrelevant answer, rate **Partially** or **No** depending on the extent of the mismatch.

i4: Accuracy of Guidance

Guiding Question: *Is the guidance provided by the chatbot factually and conceptually correct?*

This category evaluates whether the chatbot's guidance is free from factual inaccuracies and conceptual misunderstandings. A fully appropriate response demonstrates correct understanding of the concepts, procedures, or principles and presents them without errors or misleading statements.

- **Yes:** Guidance is factually and conceptually correct.
- **Partially:** Guidance is mostly correct but contains minor inaccuracies, oversimplifications, or omissions that may reduce correctness or lead to misunderstandings.
- **No:** The guidance contains major errors, is misleading, or reflects conceptual misunderstandings.

Rater Tip: Focus on correctness of claims and reasoning. Do not penalize for brevity if the guidance is accurate.

i5: Correctness of Next Steps

Guiding Question: *Are the suggested next steps or corrections accurate and appropriate to the student's problem?*

This category evaluates whether the chatbot's proposed corrections or next steps are factually accurate, conceptually sound, and well matched to the student's specific error or question. Suggestions should be correct in principle and appropriate to the given context so that following them would resolve the problem without introducing new errors.

- **Yes:** The suggested corrections or next steps are accurate and directly appropriate to the student's problem.
- **Partially:** Suggestions are generally on the right track but are incomplete, partially misapplied, or would require important missing steps to work reliably.
- **No:** Suggestions or next steps are inaccurate, infeasible, unsafe, or not aligned with the student's problem.

Rater Tip: Evaluate whether the proposed actions would solve the stated problem in the given context.

B. EXAMPLE LLM-CHATBOT RESPONSE PATTERN AND RUBRIC TRIGGERS

Table 9: Common chatbot response pattern observed in the dataset and the rubric criteria it typically triggers.

Typical response move	Primary rubric criteria triggered
Interpret the error signal (e.g., compiler/runtime message)	i1 Mistake Identification, i4 Accuracy of Guidance
Locate the source of the error in the student code	i2 Mistake Location
Explain why the error occurs and connect it to the student's implementation	i3 Providing Guidance; i4 Accuracy of Guidance
Provide actionable remediation steps (what to change and how)	i5 Correctness of Next Steps
Address additional pitfalls or edge cases (e.g., self-assignment)	i1–i4 (as applicable); i5 if a fix is proposed
Close with general best-practice reminders (e.g., Rule of Three)	Typically supports i3; may be neutral if not tied to the specific code

Annotated example (representative response):
In the dataset, the chatbot typically provides a consolidated explanation of the student's error and offers remediation steps. Responses often follow a recurring structure, which allows the rubric to be applied consistently. Below is one representative example, with each paragraph annotated by the rubric criteria it primarily triggers.

Chatbot response (example):

[**i1: Mistake Identification**]
The error message you're seeing from Valgrind indicates that there's an "Invalid write of size 8," which means that your program is trying to write to a memory location that it shouldn't. This is often due to writing to memory that has already been freed or is out of bounds of the allocated array.

[**i2: Mistake Location; i3: Providing Guidance; i4: Accuracy of Guidance**]
In your copy constructor and copy assignment operator, you're allocating a new array and then copying the elements from the `other` array. However, after repointing `arr` to the new array, you immediately delete the array that `arr` points to. This is a mistake because you're deleting the same memory you've just allocated and copied data into. As a result, when you try to access or write to this memory later, you get the invalid write error because the memory has been freed.

[**i5: Correctness of Suggestions; Clarity of Next Steps**]
To fix this, you should only delete the old array after you've done everything else, including repointing the `arr` pointer to the new array. Also, make sure that you're not leaking the previous array that `arr` pointed to before you assign it to the new array. You need to save the old pointer, assign the new array to `arr`, and then delete the old array.

Figure 5. Annotated example illustrating a common chatbot response structure and the rubric criteria it triggers.

CantoTalk: Probing Teacher Expertise From Fine-Tuned Talk Move Representations

ABSTRACT

Classroom discourse profoundly shapes student learning, yet analyzing teacher talk at scale remains challenging in non-Western and low-resource language contexts. This paper introduces CantoTalk, a dataset of 7,518 Cantonese teacher utterances from Hong Kong mathematics classrooms annotated with ten talk-move categories. We investigate whether LLMs can reliably classify these moves and encode systematic differences in teacher expertise. Fine-tuning five open-weight LLMs yields strong performance, with the best model (Qwen3-8B) achieving micro-F1 of 0.81 and macro-F1 of 0.77. Probing utterance-level embeddings reveals that teacher expertise is linearly separable with 0.79 balanced accuracy, well above chance even after controlling for surface features. Clustering analyses uncover three coherent discourse styles differing in pedagogical authority, scaffolding, and dialogic engagement, with qualitative analysis showing systematic differences in how experienced and novice teachers execute similar talk moves. These findings demonstrate that fine-tuned LLM representations capture teacher expertise, offering a new lens for analyzing classroom discourse and informing teacher feedback tools.

Keywords

Talk Move Classification, LLM Fine-tuning, Representation Learning, Teacher Expertise Detection, Low-Resource NLP, Educational Discourse Analysis

1. INTRODUCTION

Classroom discourse profoundly shapes student learning and is influenced by pedagogical traditions and cultural norms [1, 2]. Yet in typical classrooms, students contribute far less than teachers: they speak for only 27 seconds per hour of teacher talk and ask just 2 academic questions per day, compared to teachers' 142 questions [3]. Ensuring equitable classroom talk therefore depends on teachers' ability to facilitate discourse that invites reasoning, dialogue, and participation from all learners [4]. To support these goals, researchers have developed structured "talk-move" frameworks to help teachers better engage students in class and achieve their instructional objectives [5, 6]. Traditional analysis of these talk moves, however, has relied on labor-intensive manual coding methods that cannot scale to support widespread teacher development or classroom research [4].

Recent advances in large language models (LLMs) offer the potential to automate the identification of talk moves and provide immediate actionable insights to teachers [7]. However, classroom discourse remains largely an out-of-distribution domain for foundational models, which exhibit biases and misalignment to learning outcomes [8]. While there is emerging work on enhancing talk-move analysis and aligning models with pedagogical frameworks [9, 10], most studies focus on Western, English-speaking corpora and remain limited to classification tasks and frequency counts. Such analyses overlook cross-cultural adaptations of talk moves [11], the challenges of leveraging LLMs in low-resource language settings [12], as well as other contextual factors such as how teacher expertise influence discourse patterns in classroom [13].

This study therefore aims to address these gaps by examining how LLMs can identify and interpret talk moves in the authentic, low-resource setting of Hong Kong mathematics classrooms. We investigate two key research questions with CantoTalk[1]: **(1) Can LLMs be fine-tuned to perform reliable talk move classification in Cantonese classroom discourse?** and **(2) How do the distributions and linguistic realizations of talk moves differ between novice and experienced teachers, and can these patterns be uncovered from fine-tuned representations of the LLMs?**

2.1 Talk Moves in Mathematics Classrooms

"Talk moves" are utterance-level strategies used by teachers and students to elicit, clarify, or extend thinking in service of productive, dialogic learning [14]. Within mathematics instruction, these moves help navigate the tension between open-ended exploration and specific instructional objectives [5, 15]. Various frameworks have operationalized these strategies for analysis. Michaels and O'Connor [14] established a four-cluster taxonomy organized by instructional goals: encouraging students to expand their contribution, listen carefully to one another, make their reasoning explicit, and engage with others' ideas. This "Talk Moves as Tools" (TMT) framework has been widely adapted and extended. For instance, Suresh et al. [7] outline six categories: keeping everyone together, getting students to relate, restating, revoicing, pressing for accuracy, and pressing for reasoning. Research also suggests that the quality of these moves directly impacts engagement. Alic et al. [16] distinguish between "funneling" questions that guide students toward predetermined answers versus "focusing" questions that deepen mathematical thinking; while Demszky et al. [17] also highlight the importance of teacher "uptake" of student contributions, i.e., a dialogic teaching practice that acknowledges and builds upon student ideas, in ensuring students feel heard and prompted to engage more deeply with mathematical concepts.

However, these frameworks largely focus on dynamics within English-speaking classrooms; yet, the privileging of individual student talk in Western research may inadvertently undervalue other legitimate forms of mathematical communication in cultures where norms around authority, participation, and learning are different [18]. For instance, Xu and Clarke [11] demonstrate through cross-cultural analysis of Shanghai, Seoul, and Melbourne classrooms that choral responses (whole-class unison replies to a teacher's prompt) and strategic use of silence can be equally effective for developing mathematical competence, challenging assumptions that individual verbal participation is the primary indicator of engagement. Similarly, Ng et al. [19] and Ni et al. [20] highlight that in the specific context of Hong Kong mathematics classrooms, talk moves such as "inviting choral response" and "teacher evaluation" are common culturally-specific practices that put more emphasis on teacher control in advancing student's knowledge of curricular content.

2.2 Analysis of Classroom Discourse

Despite their importance, most assessments of talk moves rely on manual observation that is resource-intensive and difficult to scale [4]. Advances in computational approaches offer the potential to automate the identification and analysis of talk moves at scale [7]. With transformer-based language models, the field has progressed rapidly from early studies using small, curated datasets like TalkMoves to more robust systems trained on extensive classroom corpora such as NCTE-119 and SAGA-22 [7, 10]. The transition from Bi-LSTM architectures to BERT-based models has yielded substantial performance improvements, with reported F1-scores rising from 65% to exceeding 82% [21, 10]. More recent developments in LLMs and generative AI present new opportunities for automated feedback systems and talk move classification. While earlier studies have shown that task-specific BERT-based architectures outperform general-purpose LLMs like ChatGPT for talk move classification—a gap attributed to BERT variants learning discourse-specific cues through fine-tuning, such as turn-level patterns and move co-occurrences, that zero-shot LLMs lack [8]—the latest research suggests that fine-tuning LLMs significantly alters this landscape. For example, fine-tuned GPT-3.5-turbo models have been shown to outperform state of the art RoBERTa classifiers in identifying tutor talk moves, achieving a macro F1 score of 0.87 compared to 0.78, highlighting the critical role of fine-tuning and leveraging context (such as providing long conversation segments) to adapt LLMs effectively for the discourse analysis tasks on large-scale mathematics classroom corpora [9].

However, these advances are unevenly distributed, where developing NLP applications for low-resource languages remains challenging due to the scarcity of annotated datasets and the complexity of transferring linguistic rules from high-resource languages [22, 23]. For example, Ng et al. [24] noted that standard linguistic markers for authority (such as modal verbs) in English do not map directly to Cantonese classroom discourse, complicating the use of out-of-the-box English models. Recent benchmarks confirm that while top-tier proprietary models (e.g., GPT-4o) show emerging competence, they still exhibit significant gaps in culturally nuanced understanding and morphological generalization compared to English, with smaller open-source models lagging substantially in both fluency and accuracy when processing Cantonese colloquialisms [12]. Consequently, effective implementation requires two forms of specialization: linguistic, as Cantonese colloquialisms are under-represented in multilingual corpora [12]; and pedagogical, as culturally specific moves like *Request for Choral Response* and *Evaluation* function as authority-reinforcing practices absent from Western taxonomies [19], and thus cannot be recovered from general-purpose training alone.

2.3 Teacher Expertise and Authority

Understanding the difference between novice and experienced teachers requires examining how discourse establishes authority in the classroom: authority structures determine which talk moves are functionally available, since students are less likely to engage with reasoning demands from a teacher who has not yet established interactional authority [24]. Tong et al. [13] note that in traditional classrooms, particularly within Chinese contexts, discourse often follows an "Initiation-Response-Feedback" (IRF) pattern—where the teacher initiates a question, a student responds, and the teacher evaluates the response—which novice teachers tend to rely on to maintain control and efficiency. Experienced teachers, however, demonstrate more adaptive responsiveness, leveraging not only IRF but also "Initiation-Response-Feedback-Response" (IRFR), where the student is invited to react to the teacher's feedback, enabling a more dialogic exchange, as well as iterative initiation and response chains. Kosel et al. [25] similarly found that novice teachers tend to mostly evaluate student engagement in terms of easily observable "surface cues" (e.g., students hand-raising, digressive gaze) coupled with some cues regarding students' factual knowledge. In contrast, experienced teachers integrate a broader spectrum of not only "surface cues" but also "deep cues" (e.g., students' motivation, attentiveness, confidence, quality of verbal contributions) when diagnosing

student engagement and gauging instructional effectiveness. These findings point to the importance of accounting for not just the presence of talk moves, but how teachers configure authority and engage students within specific cultural and classroom norms.

3. DATA

The dataset used in this study is derived from classroom recordings originally collected by Ni et al. [26]. We refer to this annotated corpus as CantoTalk, which comprises 7,518 teacher utterances (M = 48.19, SD = 57.62 characters) and 7,088 student utterances (M = 7.36, SD = 10.60 characters), drawn from 64 recorded and transcribed lessons across 32 upper-primary mathematics teachers in 16 Hong Kong schools, with each teacher providing 2 lessons [26]. These utterances were labeled using a ten-category scheme designed by Ng et al. [19], including: *Ask for Expression*, *Say More*, *Revoice*, *Press for Reasoning*, *Repeat and/or Add On*, *Agree/Disagree*, *Explain Others*, *Request for Choral Response*, *Evaluation*, *Other Moves* (see Appendix A for full definition and examples).

The scheme is built upon established discourse frameworks, including Talk Moves as Tools (TMT), Classroom Discourse Analyser (CDA), authority theory, and accountability principles in productive disciplinary engagement [27, 14, 28, 29, 30], with the addition of *Request for Choral Response* and *Evaluation* to reflect the structured teacher-led nature of Hong Kong mathematics classrooms and the use of collective participation to reinforce curricular knowledge [19]. The dataset was manually annotated by the researchers of the original study, achieving inter-coder agreement ranging from 0.7 to 1.0 [26]. Appendix Table A provides a complete list of talk move labels, and their descriptions.

Teacher metadata includes years of teaching experience ranging from 1 to 23 years (see Figure 1), grade level(s) taught, and school context. We categorized teachers into novice ($\leq$ 5 years, n = 8, 2110 utterances), intermediate (6–9 years, n = 7, 1922 utterances), and experienced ($\geq$ 10 years, n = 17, 3506 utterances) based on experience thresholds established in the teacher development literature. For our expertise detection analyses, we excluded intermediate teachers to maximize contrast between groups, yielding a final dataset of 5,616 utterances with a 62.4% experienced to 37.6% novice ratio. We note that years of experience serves as a coarse proxy for instructional expertise, as experience correlates with expertise only probabilistically and nonlinearly. We adopt this operationalization pragmatically, as direct measures of instructional quality were not available in the dataset, and interpret all expertise-related findings with this caveat in mind.

This dataset, which we refer to as CantoTalk, including all teacher and student utterances with talk-move annotations, contextual windows, and teacher metadata (anonymized experience levels, grade levels taught) is hosted on the GitHub repository.

4. METHODS

We adopt a two-stage approach. First, we fine-tune a set of open-weight LLMs from different research groups and parameter scales to identify the best-performing model for talk-move classification. Second, using the top model, we extract utterance-level embeddings to compare discourse patterns between novice and experienced teachers. Teachers with 6–9 years were excluded from embedding comparison analyses. Note that we initially explored few-shot prompting using off-the-shelf LLMs, such as Deepseek-R1 and Gemini-2.5-Pro to classify teacher talk moves, but excluded this method from our final analysis as it yielded suboptimal performance ($F_1 < 0.35$) & proved computationally prohibitive, requiring over one hour per transcript.

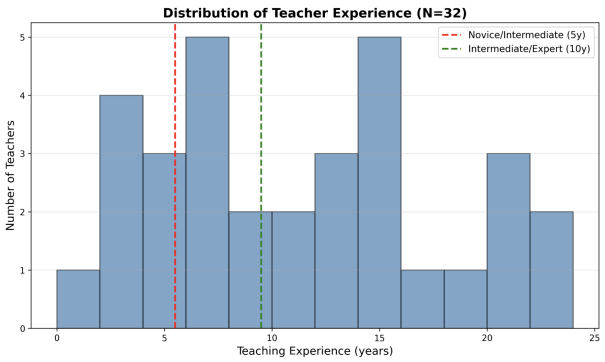

Figure 1: Distribution of teacher experience in years.

4.1 Fine-tuning

Training Data Construction. We perform a transcript-level split (70% train, 15% validation, and 15% test) to ensure that no utterance's immediate conversational context spans across splits, preventing direct context leakage between classroom sessions. Only teacher-labeled utterances are used. Because talk-move classification is strongly context dependent, each training instance is constructed using a ±6 utterance sliding window containing six preceding turns, the focal utterance, and six following turns, formatted as `<speaker>: <content>` pairs to preserve turn-taking structure. Examples without a full context window are discarded.

Prompt Format. All models receive prompts in a standardized chat format: a Cantonese (i.e., Traditional Chinese) instruction, the full set of talk-move definitions (Cantonese + English), and the contextual dialogue grouped into preceding, current, and following blocks, followed by a directive to output all applicable talk-move categories as a comma-separated list. Chat templates for the chosen models differ only in formatting tokens, and the informational content in all of them is identical. Full prompts are presented in Appendix B.

Models and Training Procedure. We fine-tune five open-weight LLMs, including: `Qwen3-4B-Instruct-2507`, `Qwen3-8B`, `Llama-3.1-8B-Instruct`, `DeepSeek-V3.1`, and `GPT-OSS-20B` using Tinker API [31]. All models are trained using LoRA adapters (rank = 32) with a batch size of 8 and a maximum input length of 4096 tokens. Adam optimization was used with a 300-step linear warm-up. The model trained for up to 3000 steps with early stopping on validation loss. Training hyperparameters are listed in Appendix C. To address severe skew in talk-move frequencies, we ap-

ply inverse-frequency loss weighting, assigning each label i weight $w_i = (1/f_i)^{0.5}$, normalized to have mean 1.0. For multi-label examples, we use the maximum weight among the associated labels. This weighting scheme amplifies the contribution of rare moves such as *Explain Others* and *Evaluation*.

Evaluation. Evaluation is conducted on held-out teacher utterances. Models generate label sequences using deterministic decoding (temperature = 0). Predictions are canonicalized by splitting on commas, trimming whitespace, and matching against the valid label inventory (see full details in Appendix D). We report: micro-F_1, micro precision, micro recall, macro-F_1 (averaged across labels) and per-label F_1 and support.

4.2 Embedding Analysis

Embedding Extraction. We analyze internal representations from our best-performing model to examine whether it encodes systematic differences between novice and experienced teachers. A well-known challenge in probing LMs is that pooling token embeddings over the entire prompt can entangle properties of the target utterance with artifacts from the surrounding instructions and definitions [32]. To avoid this, we extract target-only embeddings using character-level offset mappings.

For each example, we tokenize the full prompt (instruction + talk-move definitions + before/after context + target utterance) with `return_offsets_mapping=True`. We identify the character span of the target utterance using fixed delimiters (當前發言： ... 後文語境：) and select only the tokens whose offsets overlap this region. The embedding of the utterance is computed by mean-pooling the final-layer hidden states of these tokens. We use the last transformer layer because it typically captures task-specific refinements acquired during fine-tuning [33, 34]. This procedure yields a 4,096-dimensional embedding for all 7,538 utterances in the corpus. Extraction is performed via Colab Pro on an NVIDIA A100 using 8-bit quantization, enabling full processing in approximately 40 minutes.

Dimension Validation and Feature Selection. For expertise analyses, we retained only novice and experienced teachers, resulting in an embedding matrix of size $5{,}616 \times 4{,}096$. To identify dimensions associated with teacher expertise while avoiding overfitting, we divide them into a stratified 80/20 train-test split. On the training set, we conduct two-sample t-tests comparing experienced versus novice values across all 4,096 dimensions, applying a Bonferroni-corrected threshold ($\alpha = 1.22 \times 10^{-5}$). This yields 1,254 significant dimensions (30.6%). We re-test these dimensions on the held-out set at the same threshold; 348 dimensions (27.8%) remain significant. This two-stage procedure separates dimension validation from classifier training, enabling us to probe what the model encodes rather than just maximize classification accuracy, while guarding against dimensions that are spuriously significant in the training set alone. All downstream analyses use only these validated dimensions.

Expertise Classification. Overall, we train a linear probe implemented as an ℓ_2-regularized logistic regression classifier (`solver = lbfgs`, $C = 1.0$, `max_iter = 1000`) with balanced class weights to correct for class imbalance, using the validated 348-dimensional embeddings as features. All inputs are standardized (z-scored). We conduct 5-fold stratified cross-validation on the training set ($n = 4{,}492$) and evaluate the final model on the test set ($n = 1{,}124$). We report accuracy, balanced accuracy, precision, recall, and F_1. This analysis identifies whether the model's internal representations reliably encode distinctions between novice and experienced teachers. On a talk-move level, to test whether expertise is uniformly encoded across discourse practices, we repeat the probe analysis for each of the nine primary talk-move categories (excluding *Other Moves* as it contains varied moves). For each move, we subset the data to utterances containing that move, then train the same logistic regression classifier with 5-fold CV. We evaluate significance by one-sample t-tests against chance ($\mu = 0.5$) using balanced accuracy as the metric. This analysis identifies which pedagogical moves are most diagnostic of teacher expertise.

Clustering. To explore latent discourse patterns beyond binary expertise classification, we perform k-means clustering on the 348-dimensional validated embeddings. We compare solutions for k = 2–10 using silhouette [35], Calinski-Harabasz [36], and Davies-Bouldin [37] scores to choose k = 3. The association between cluster membership and expertise is tested with a χ^2 test, with structure visualized using UMAP [38] (`n_neighbors = 15`, `min_dist = 0.1`). To interpret the discovered clusters, we compute descriptive properties of each cluster such as proportion of experienced teachers, mean utterance length, and talk moves in it.

We further assess linguistic and pedagogical differences across clusters through several analyses. First, we compare utterance lengths using a one-way ANOVA and report η^2 effect sizes; post-hoc differences are examined with Bonferroni-corrected Mann-Whitney U tests. To evaluate whether cluster structure is driven by verbosity rather than discourse function, we train a shallow decision tree (`max_depth = 2`) to predict cluster membership using only utterance length, quantifying how much representational structure remains after accounting for this surface feature. Next, we conduct a qualitative comparison of experienced and novice utterances within each cluster to examine differences in execution quality beyond move frequency or length. These combined analyses triangulate the linguistic and pedagogical properties that define the discovered embedding clusters.

5. RESULTS

5.1 Fine-tuning

Table 1 reports test-set performance for all five fine-tuned LLMs. `Qwen3-8B` achieves the strongest results, obtaining the highest micro-F_1 (0.8145) and macro-F_1 (0.7687). Although `Qwen3-8B` outperforms `DeepSeek-V3.1` narrowly despite comparable size, we select `Qwen3-8B` for subsequent embedding analyses due to: (a) its slightly superior accuracy and (b) lower computational cost owing to its smaller size. `Qwen3-4B-Instruct-2507` and `Llama-3.1-8B-Instruct` form a middle tier, outperforming `GPT-OSS-20B` but trailing the top models by several points. `GPT-OSS-20B` underperforms across all metrics despite its larger parameter count.

Per-Label Performance. Table 2 shows per-label F_1 scores for `Qwen3-8B`. The model performs best on moves with strong

Table 1: Performance of FT models on talk-move classification

Rank	Model	F_1^{μ}	F_1^{M}	Prec.	Rec.
1	Qwen3-8B	**0.8145**	**0.7687**	0.8048	**0.8245**
2	DeepSeek-V3.1	0.8134	0.7401	0.8077	0.8193
3	Qwen3-4B-Instruct-2507	0.7959	0.7221	**0.8097**	0.7827
4	Llama-3.1-8B-Instruct	0.7927	0.7432	0.8020	0.7837
5	GPT-OSS-20B	0.5683	0.4164	0.7624	0.4529

Table 2: Per-label F_1 scores for talk-move classification by Qwen3-8B. Support indicates the number of test examples

Talk Move Label	F_1	Support
表達自己 (Ask for Expression)	0.823	620
對自己發言作補充 (Say More)	0.858	219
複述 (Revoice)	0.860	625
解釋自己 (Press for Reasoning)	0.742	353
重述及/或補充他人發言 (Repeat and/or Add On)	0.739	253
同意/否定 (Agree/Disagree)	0.788	90
解釋他人 (Explain Others)	0.545	5
集體作答 (Request for Choral Response)	0.884	444
評價 (Evaluation)	0.678	55
其他 (Other Moves)	0.768	396
Macro Average	**0.7687**	**3,060**

contextual cues and larger support, such as *Say More*, *Revoice*, and *Request for Choral Response*, each reaching F_1 scores above 0.85. In contrast, the lowest F_1 scores correspond to categories with extremely sparse support. Noticeably, *Explain Others* has $F_1 = 0.545$ (5 instances in the test set), and *Evaluation* has $F_1 = 0.678$ (55 instances in the test set), showing reduced performance. These patterns reflect the long-tail distribution of pedagogical moves as well as their inherent semantic difficulty, which can make some moves harder to distinguish than others.

5.2 Embedding Analysis

We present results in two phases: first, expertise classification demonstrates that teacher expertise is linearly recoverable from the model's internal representations; second, cluster analysis reveals the pedagogical structure underlying these representations.

Expertise Classification. For overall set, a linear probe trained on 348 validated dimensions achieved 0.733 ± 0.016 balanced accuracy (5-fold CV) and 0.790 on held-out test data, significantly above chance (0.50). The model distinguished both experienced ($F_1 = 0.83$) and novice ($F_1 = 0.74$) discourse effectively, indicating that performance was not driven by class imbalance exploitation. These results establish that teacher expertise is linearly encoded within the model's representational geometry, a key finding suggesting that teacher experience leaves distinctive signatures in fine-tuned embeddings. We repeated probe analysis separately for each talk-move category to determine whether expertise signals vary by pedagogical function. All categories showed above-chance balanced accuracy (mean = 0.754; all > 0.70), but with meaningful variation. *Revoice* (0.783), which involves deeper interpretation of student thinking to paraphrase contributions, had the highest differentiation. In contrast, *Press for Reasoning* had the weakest differentiation (0.723). This pattern suggests the model captures expertise-sensitive nuances within all talk moves.

Cluster Discovery. K-means clustering on the 348 dimensions revealed three stable discourse clusters. A χ^2 test showed strong association with expertise ($\chi^2 = 256.7$, $p < 10^{-56}$), indicating that representational regions in the embedding space differ by teacher expertise. UMAP projections (Figure 2) reveal that the three clusters occupy largely distinct regions of the embedding space, with overlap concentrated at cluster boundaries, consistent with the natural co-occurrence of talk moves across discourse styles. To ensure that clusters truly reflected pedagogical function rather than surface-level verbosity, we conducted three validation tests. First, while clusters differed significantly in average length ($p < 10^{-145}$, $\eta^2 = 0.112$), a decision tree using only length as a predictor achieved just 65% accuracy in cluster assignment, misclassifying 35% of utterances and showing particular confusion between Clusters 2 and 3 despite their 38-character mean length difference (29.1 vs. 67.3 characters). Second, within each cluster, experienced and novice utterances showed no significant length differences (Cluster 1: $p = 0.23$; Cluster 2: $p = 0.67$; Cluster 3: $p = 0.18$), yet maintained distinct embedding patterns as evidenced by the linear probe's within-cluster classification performance. Third, experienced-novice differences in pedagogical moves persisted within each cluster even when length was held constant. These findings collectively demonstrate that embedding geometry captures deeper distinctions in discourse rather than mere stylistic artifacts.

Cluster Characterization. Through qualitative analysis of utterances within clusters, we found they capture qualitatively different instructional styles. Critically, these clusters are defined not just by which moves are used, but by *how* they are executed. The embedding space appears to align with well-established pedagogical constructs, including authority and accountability roles in classroom discourse, cognitive-demand frameworks, and distinctions between monologic, authoritative, and dialogic instructional patterns.

Cluster 1: Procedural Management Integrated with Conceptual Scaffolding ($n = 118$; experienced 78%; $M = 97.8$ chars). This cluster represents long, multi-functional turns where teachers intertwine classroom management and procedural explanations with mathematical content. We note that Cluster 1 is notably smaller than the other clusters and appears less stable in the UMAP projection, which likely reflects the relative rarity of long multi-functional turns in the corpus rather than a poorly-defined cluster; internal validation metrics (silhouette, Calinski-Harabasz, Davies-Bouldin) consistently supported $k = 3$ over alternative solutions. Experienced teachers frequently turn routine instructions into opportunities for conceptual elaboration. For instance, while managing a hands-on activity in which students were cutting paper shapes to explore symmetry, one experienced teacher turned a management moment into a mathematical one: *"No, this is not a symmetrical figure... don't be like Student 4 who cut it—once it's cut, it's no longer a parallelogram."* Rather than separating the procedural warning from the mathematical concept, the teacher

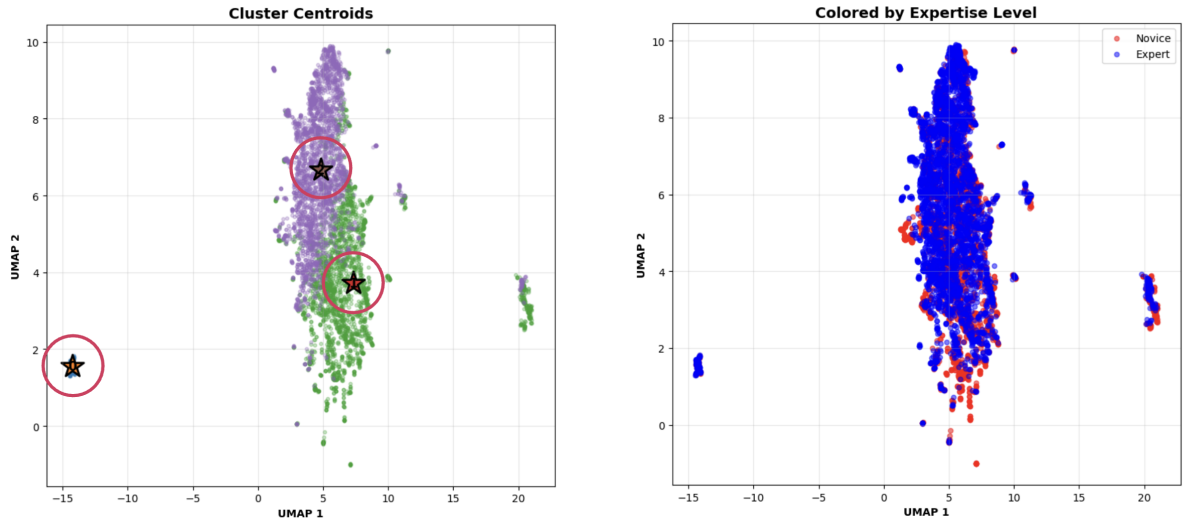

Figure 2: UMAP projection of utterance embeddings showing three discourse clusters ($k = 3$). Colors indicate cluster membership; clusters differ in expertise concentration (78%, 51%, 72%).

delivers both within a single turn. Even in explaining partitioning procedures, experts weave in conceptual reframing: *"If I split this into two equal parts, this is no longer just 'one'—what is it then?"*, inviting reconceptualization of unit size. By contrast, novice teachers issue procedural instructions as distinct steps separate from conceptual elaboration: *"Mixed numbers... I'm just going to transform one of the parts... how many equal parts should I cut it into?"* Cluster 1 represents a mode where instructional guidance and content delivery occur simultaneously, with experts more likely to weave these functions within single turns while novices sequentialize them.

Cluster 2: Rapid-Fire Elicitation and Checking (n = 2,598; experienced 51%; M = 29.1 chars). This cluster contains short prompts dominated by *Ask for Expression* and *Request for Choral Response*, aligning with IRE (Initiate-Response-Evaluate) patterns observed in the regional context [26]. Both experienced and novice groups use this mode frequently, but for different functions. Experts often reinforce structural relationships: *"The denominators are the same—meaning the addend and augend denominators are both...?"* While novices also employ short questioning sequences to elicit mathematical reasoning (*"Three over six. Why is it three over six?"*), they more often emphasize reinforcing recall or ensuring procedural correctness. Prompts like *"Say it again completely"* or *"Read it carefully. Read it carefully"* focus on the form or mechanics of participation [25]. Questions such as *"That's right—what is the question actually asking you to use?"* verify task comprehension. While both groups leverage rapid-fire turns to probe concepts, novices pay more attention to ensuring students follow procedures correctly.

Cluster 3: Dialogic Facilitation and Inquiry (n = 2,900; experienced 72%; M = 67.3 chars). This cluster represents medium-length turns where teachers orchestrate mathematical discourse by positioning students as sources of knowledge and facilitating peer reasoning. Teachers frequently employ *Press for Reasoning*, *Agree/Disagree*, and *Repeat and/or Add On* moves that redistribute mathematical authority across the classroom. While both groups encourage student expression and peer explanation, discernible differences emerge in their approaches. Experts probe underlying mathematical logic (*"Why did you do it so fast? Tell me, when you were measuring, how did you measure so quickly?"*), while novices often couple explanation-seeking with classroom management (*"Student 21 stand up, what is he saying?"*, *"When classmates are talking, you need to listen carefully"*). Experts frame inquiry to elevate student status (*"What's the secret to making you count so fast? Let me interview the fastest group first"*) and persist in understanding reasoning (*"I don't really understand what Student 22 is saying. Can you say it again?"*), while some novices redirect when students struggle (*"I don't know what you're talking about!"*). In short, Cluster 3 reflects attempts to democratize mathematical authority, however, teachers may vary in their approaches to sustain productive student-centered dialogue.

6. DISCUSSION

This study shows that fine-tuned LLMs can reliably classify talk moves in Cantonese mathematics classrooms and that their internal representations encode systematic differences in teacher expertise. A key contribution of our approach is its ability to surface pedagogical structure that is difficult to specify in advance. Traditional linguistic analyses require researchers to pre-select features such as question types, turn lengths, or lexical indicators, and may therefore miss diffuse or non-obvious cues to expertise. Embedding analysis instead reveals the latent distinctions the model uses to separate discourse from experienced and novice teachers, capturing how ideas are composed, how teachers respond to unfolding interaction, and how the same move is executed differently. Analysing representations thus provides a complementary lens on classroom instruction. We discuss three key contributions of our study and their implications below.

Fine-Tuned Models Enable Cross-Cultural Discourse Analysis. Domain-specific fine-tuning yielded strong talk-move classification performance. Qwen3-8B achieved micro-F_1 = 0.814 and macro-F_1 = 0.768, with particularly high accuracy on culturally characteristic moves such as *Request for Choral Response* (F_1 = 0.884) and *Revoice* (F_1 = 0.860). These results indicate that open-weight models, when properly adapted, can learn context-specific pedagogical practices that differ from Western instructional norms, an encouraging outcome given that Cantonese remains severely under-represented in NLP resources. Notably, models larger than 8B parameters did not yield meaningful improvements, suggesting that performance gains came primarily from adaptation rather than scale alone; this is further supported by our few-shot prompting baseline using off-the-shelf LLMs, which yielded $F_1 < 0.35$ without fine-tuning, compared to 0.81 after adaptation. We did not evaluate larger multilingual LLMs such as Qwen3-235B due to computational constraints. Nonetheless, the underperformance of `GPT-OSS-20B` relative to smaller fine-tuned models hints that scale alone may not fully compensate for domain adaptation in low-resource pedagogical settings. Evaluating larger multilingual models as zero-shot baselines remains an important direction for future work.

LLM Embeddings Encode Expertise Beyond Surface Features. Before interpreting these results, we note that our operationalization of expertise as years of experience is a known limitation. Experience correlates with instructional quality only probabilistically, and the relationship is nonlinear: some novices exhibit expert-like discourse and vice versa. The patterns we report should therefore be understood as differences between less and more experienced teachers, not as validated markers of instructional quality per se. Embedding analysis showed that teacher expertise is linearly recoverable from the model's internal representations (balanced accuracy = 0.790 on held-out data). Expertise signals were strongest for moves involving deeper reasoning, such as *Revoice* (0.783), and weaker for procedurally simpler moves. K-means clustering revealed three coherent discourse styles: (1) procedural management and scaffolding (78% expert), (2) rapid elicitation (51% expert), and (3) dialogic facilitation (72% expert). Although lengths of utterances within the clusters differed, our results show that length is not driving the structure, and deeper pedagogical signals underlie the observed geometry. Qualitative inspection supports this interpretation. Experts and novices often use similar structures, but experts integrate conceptual connections. In Cluster 2, for instance, experts extend student thinking ("The denominators are the same…"), whereas novices default to repetitive prompting ("Say it again completely"). This computational pattern mirrors educational research showing that experienced teachers exhibit stronger adaptive responsiveness and conceptual coherence [25, 13].

Implications for Automated Teacher Feedback. The linear separability of teacher expertise in embedding space provides a foundation for formative feedback tools that move beyond counting talk-move frequencies. Rather than treating discourse categories as checklists, automated systems could surface differences in how similar moves are executed, identify low-quality realizations of otherwise appropriate moves, highlight overreliance on novice-dominant discourse patterns, or suggest examples from experienced-teacher clusters as models for improvement. For instance, our Cluster 2 analysis shows that both novice and experienced teachers frequently use rapid questioning, but differ in pedagogical function: novices tend to emphasize procedural compliance, while experienced teachers use similar moves to surface underlying mathematical structure. This illustrates that the instructional value of a talk move lies in its realization, not its label.

These differences suggest concrete opportunities for targeted coaching in teacher education. Contrasting examples drawn from our discourse clusters could help novice teachers recognize how small shifts in phrasing, sequencing, or follow-up change the function of a move. Rather than generic advice such as "ask more open-ended questions," professional development can focus on specific discourse strategies, such as sustaining student reasoning through clarification and revoicing when confusion arises. Grounding coaching in authentic classroom utterances may make otherwise tacit aspects of instructional expertise more visible and learnable.

At the classroom level, these insights point toward personalized, low-stakes feedback tools that support reflection over time. Session-level summaries showing how a teacher's utterances distribute across discourse clusters, paired with illustrative examples from experienced-teacher patterns, could help teachers identify missed opportunities for conceptual scaffolding or overreliance on rapid elicitation. When framed as developmental reference points rather than evaluative benchmarks, such feedback can complement self-reflection and support growth across a semester.

Finally, by making explicit the discourse norms embedded in Hong Kong mathematics classrooms, this work opens space for cross-context professional dialogue rather than prescriptive standardization. Educators in different settings can use these representations to examine their own assumptions about participation, questioning, and authority, such as the role of choral response in collective sense-making [11, 19]. When carefully contextualized, automated discourse feedback can support reflection and learning across instructional contexts.

7. LIMITATIONS

We acknowledge several limitations of this study. First, our embedding analysis was conducted exclusively on Qwen3-8B. While this choice was methodologically justified, it means that our findings may be model dependent. Models with different capacities or architectures may encode talk-move patterns in different ways, which limits the generalizability of our results across LLM families. Additionally, our embedding extraction approach relies on delimiter-based span detection and token-to-character offset mapping, which assumes consistent tokenizer behavior and accurate recovery of span boundaries. In practice, any misalignment, particularly in non-space-delimited languages, may result in partial contamination from surrounding context. Disentangling whether low F1 on rare categories such as *Explain Others* and *Evaluation* reflects data sparsity or intrinsic semantic difficulty also remains an open question, and controlled subsampling experiments matching support across labels would be a valuable direction for future work.

Second, this study operationalizes instructional expertise as years of teaching experience, a coarse proxy whose limitations are discussed in Sections 3 and 6. A related concern involves the effective sample size of the expertise analyses: although CantoTalk contains over 7,000 utterances, these come from only 32 teachers, with expertise analyses contrasting just 25 teachers after excluding the intermediate group. The observed embedding-based distinctions may therefore partly reflect teacher-specific idiosyncrasies rather than robust markers of expertise; replication with a larger and more diverse teacher sample remains an important next step. Additionally, intermediate teachers were excluded from classification analyses to maximize contrast between novices and experts; whether embeddings order all three experience levels approximately linearly is also an open question for future work.

Finally, the teacher utterances analyzed in this work come from a narrow instructional domain, namely mathematics classrooms in Hong Kong. As a result, the discourse patterns that the model learns to associate with expertise may reflect local or context-specific norms rather than generalizable features of high-quality instruction. Findings may not generalize to other subjects, cultures, or languages. Additionally, although we identify embedding clusters that correlate with differences in teaching experience or talk-move styles, we do not establish a direct connection to student learning outcomes. While our results show that LLM embeddings encode systematic differences between novice and experienced teachers in ways that align with theoretical constructs from the teacher development literature, we do not evaluate whether identified expertise patterns actually support student learning, engagement, or equitable participation. It is possible that some of the discourse patterns we label as "expert" reflect institutional norms, curriculum alignment, or classroom management strategies rather than practices that promote deeper learning. For example, frequent use of *Request for Choral Response* may create an appearance of engagement without supporting individual sense-making. Future work should incorporate behavioral measures or expert-based validation and extend the analysis to a wider range of instructional contexts.

8. ETHICAL IMPLICATIONS

Some important ethical implications of this research include:

Privacy and Consent. This work relies on classroom discourse data, which raises important privacy concerns. Although all transcripts were anonymized and stripped of identifying information, teaching styles and discourse patterns may still be recognizable to colleagues within the same context. We mitigated this risk through anonymized analysis, and any future deployment of similar models should adopt strict data governance practices and explicitly prohibit individual teacher identification.

Potential Benefits. This work has several positive implications for education research and practice. Automated analysis of talk moves could support scalable, low-cost professional development by enabling teachers to reflect on their discourse patterns over time. By demonstrating that LLMs can be adapted to non-Western, non-English classroom contexts, this study also contributes toward more inclusive educational technologies and reduces reliance on English-centric tools. For researchers, automated classification substantially lowers the cost of large-scale discourse analysis, opening opportunities for longitudinal and cross-context studies that are infeasible with manual coding.

Risks and Misuse. At the same time, this work carries meaningful risks. Discourse patterns should not be treated as a complete or universal measure of teaching quality, yet there is a risk that such tools could be misused for high-stakes evaluation. Teaching quality is multidimensional and context-dependent, and many critical aspects of instruction are not captured in transcripts alone. There is also a risk of reinforcing narrow pedagogical norms learned from specific frameworks and contexts, which may not generalize or align with local instructional values. Additionally, because we do not validate our findings against student learning outcomes, identified expertise patterns may reflect institutional norms or surface-level engagement rather than deep learning.

Fairness and Generalization. Our use of teaching experience as a proxy for expertise introduces fairness concerns, as experience does not always align with instructional quality. The model may misclassify effective novice teachers or disadvantage teachers working in more challenging contexts. Furthermore, because the data come from Cantonese-medium mathematics classrooms in Hong Kong, the learned patterns reflect local discourse norms and linguistic features that may not transfer to other subjects, cultures, or languages.

Responsible Use. We emphasize that models like ours should be used only for low-stakes, teacher-initiated reflection, not for administrative evaluation or accountability. Future work should validate discourse signals against student outcomes, involve educators as co-designers in new contexts, and treat automated analysis as a complement to, rather than a replacement for, human professional judgment.

APPENDIX

A. TALK MOVES FRAMEWORK

Teacher talk-move labels, their definition, function and examples, presented in Appendix Tables A. We would like to note that teacher talk move definitions, functions, and examples are synthesized from [39], [24] and [19].

Table A.1: Teacher Talk Moves with Definitions and Illustrative Examples

Talk Move	Definition	Examples
表達自己 (Ask for Expression)	明確邀請學生把想法說出來（不限內容深度）。 *Teacher invites a student to state their thinking or idea (no reasoning required).*	"Could you tell me what features a quadrilateral has?" "If they are the same, this procedure is what we call...?"
對自己發言作補充 (Say More)	要求同一位學生把剛才的發言延伸或補充細節。 *Teacher asks the same student to elaborate on their own prior statement.*	"Talk a little bit more." "Could you Say More about the idea you've just expressed?" "Is there anything you want to add about your example?"
複述 (Revoice)	老師用自己的語言重述學生想法以確認理解或放大訊息。 *Teacher restates a student's idea in their own words to confirm understanding or clarify for others.*	"So, let me see if I've got your thinking right. Are you saying...?" "Student X told us a square should have four equal angles." [Student: "Three parts."] "Three parts—so which one is three-eighths now?"
解釋自己 (Press for Reasoning)	追問同一學生說明「為什麼／怎麼知道」。 *Teacher asks a student to explain the reasoning behind their answer.*	"Why do you think that?" "What's your evidence?" "Could you describe the procedure she used?"
重述及/或補充他人發言 (Repeat and/or Add On)	邀請學生重述同伴想法，或在其上加以補充。 *Teacher invites students to restate or add to another student's idea.*	"Could you provide an example to illustrate the definition he is giving?" "Anything wrong with that answer, Student X?"
同意/否定 (Agree/Disagree)	老師表態同意或否定學生想法。 *Teacher expresses agreement or disagreement with a student's idea.*	"Do you agree/disagree—and why?" "Do you accept his example as a quadrilateral figure?"
解釋他人 (Explain Others)	要求學生解釋「另一位」的推理或方法。 *Teacher asks a student to explain the reasoning of another student.*	"Why do you think he said that?" "Who can explain what she means when she says that?"
集體作答 (Request for Choral Response)	要求全班齊答。 *Teacher prompts the whole class to respond together.*	"Do we all agree with that?" "The first multiple of a number is... say it together!"
評價 (Evaluation)	老師給出正誤判斷、稱讚或等第式回饋。 *Teacher provides correctness judgment, praise, or evaluative feedback.*	"You're right." "Good idea." "Not exactly correct."
其他 (Other Moves)	不屬上述類別的管理、過渡、後勤或其他話語。 *Classroom management, procedural talk, transitions, etc.*	"Please do not talk to your neighbor." "Open your textbook to page 25 for homework." "Louder, I couldn't hear just now."

B. FULL PROMPT TEMPLATE

Each training example is formatted using the model's native chat template, with identical informational content across architectures. Below is the canonical prompt used for all models (Cantonese + English definitions).

B.1 User Message

分析以下香港高小數學課堂對話，識別當前發言的所有talk move類別。
Talk Move 類別定義：

- `{label_1}`: `{definition_1}`
- `{label_2}`: `{definition_2}`
- ...
- `{label_k}`: `{definition_k}`

前文語境：
`{speaker_before_1}`: `{utterance_before_1}`
`{speaker_before_2}`: `{utterance_before_2}`
`{speaker_before_3}`: `{utterance_before_3}`
`{speaker_before_4}`: `{utterance_before_4}`
`{speaker_before_5}`: `{utterance_before_5}`
`{speaker_before_6}`: `{utterance_before_6}`
當前發言：
`{current_speaker}`: `{current_utterance}`
後文語境：
`{speaker_after_1}`: `{utterance_after_1}`
`{speaker_after_2}`: `{utterance_after_2}`
`{speaker_after_3}`: `{utterance_after_3}`
`{speaker_after_4}`: `{utterance_after_4}`
`{speaker_after_5}`: `{utterance_after_5}`
`{speaker_after_6}`: `{utterance_after_6}`
任務：根據上述定義，識別當前發言的所有適用talk move類別（用逗號分隔多個類別）。

B.2 Assistant Message

Gold multi-label target:

`<label_1>, <label_2>, ...`

B.3 Model-Specific Renderers

- `Qwen3-4B-Instruct-2507, Qwen3-8B` → `qwen3_instruct`
- `Llama-3.1-8B-Instruct` → `llama3_instruct`
- `DeepSeek-V3.1` → `deepseek`
- `GPT-OSS-20B` → `gpt_oss_no_sysprompt`

Note: Renderers differ only in tokenization wrappers; content is identical.

C. TRAINING HYPERPARAMETERS

All models were fine-tuned using LoRA adapters with the following configuration:

Component	Setting
LoRA Configuration	rank = 32; α = model default; dropout = 0.0
Optimizer	Adam ($\beta_1 = 0.9$, $\beta_2 = 0.95$, ϵ = 1e–8)
Learning Rate	base LR = 2e–5; LoRA LR scaled via `get_lora_lr_over_full_finetune_lr()`
Scheduling	300-step linear warm-up; constant LR thereafter
Training Steps	max 3000 steps; early stopping after 5 validation checks
Validation	every 100 steps (100-sample subset)
Batch Size	8
Sequence Length	max 4096 tokens
Checkpointing	every 50 steps

Table C.1: Hyperparameter configuration for LoRA fine-tuning across all models.

D. IMPLEMENTATION AND EVALUATION DETAILS

Tokenization and Truncation. We use each model's native tokenizer (via Tinker's `get_tokenizer()`), truncating sequences to a maximum length of 4096 tokens. Truncation is applied only to the earliest portions of the preceding context, ensuring that the focal utterance and its immediate surroundings are always preserved.

Decoding. During evaluation, models generate predictions using greedy decoding (temperature = 0) with a 50-token limit and model-specific stop sequences. Outputs are stripped of special tokens before post-processing.

Label Canonicalization. Generated text is split on commas, normalized (whitespace removed), and matched to the valid talk-move inventory. Unknown strings are discarded. Multi-label predictions are converted into binary indicator vectors for evaluation.

Characterizing Students' LLM Usage Behaviors and Their Association with Learning in Critical Thinking Tasks

ABSTRACT

Large language models (LLMs) are becoming increasingly embedded in students' learning practices, yet much of what is known about how students use LLMs and how this usage impacts learning comes from problem-solving domains or constrained experimental settings. We present an analysis of data on LLM usage collected during two offerings of a research-oriented course where students learn to read, reason about, and critique academic papers. Without restrictions on whether or how to use LLMs, students reported their LLM usage practices when asked to do these activities as a series of homework assignments during the course. This paper extends prior work done on data from a single offering of the same course by presenting a refined bottom-up categorization of LLM usage types, cross-labeled by the extent of student initiative these usages entail. Furthermore, we examine how LLM use impacts student learning, measured by performance on three midterms, looking at factors such as frequency and type of usage.

Keywords

Students' LLM Usage Behaviors, Bottom-up Categorization, Association with Learning

1. INTRODUCTION

As large language models (LLMs) become more powerful, sophisticated, and accessible, the educational community continues to grapple with understanding what roles these models can and should play in education [21, 13, 11]. While some argue that integrating LLMs into coursework offers benefits such as immediate and personalized feedback [21, 13], there are widespread concerns that using LLMs may undermine students' learning, prompting calls to prohibit its use until we gain a better understanding of how it can be effectively leveraged (e.g., [11]). This paper contributes to a growing body of research addressing the critical need to understand how students use LLMs in practice and how such use may support or hinder learning.

Much of the existing research on student usage of LLMs has focused on problem-solving domains, particularly programming [21, 13, 16, 2, 9, 5, 1]. These domains tend to emphasize solution-seeking and correctness, which has led prior work to frame LLM use primarily in terms of debugging or generating solutions and answers. In contrast, many general academic skills—such as reading, reasoning, and critical thinking—require interpretation, judgment, and the construction of understanding rather than arriving at a single correct solution. In such contexts, LLMs may shape how students think and engage with material in more nuanced ways that are not well captured by studies centered on problem-solving tasks.

Another limitation of prior work on students' use of LLMs is that many studies rely on controlled experiments or structured interventions, where students are instructed to use LLMs in predefined or constrained ways. Although some work has examined LLM use in authentic course assignments [7], students were still guided toward specific forms of interaction, which may not reflect how they would naturally choose to use LLMs.

In this paper, we investigate LLM use in a learning context that has received little prior attention: a research-oriented course in which students learn to read, reason about, and critique academic papers. We examine students' LLM use during two offerings of a real university course by drawing on students' self-reported usage in weekly assignments, which allow us to capture organically occurring LLM use within an in-the-wild classroom setting where students were free to decide whether to use LLMs and how to use it. The analysis presented in this paper extends prior work on data from a single offering of the same course [15]. We adopt a similar bottom-up, data-driven approach which characterizes LLM use based on students' actual reported practices rather than prescribed behaviors or predefined categories, but we present a refined bottom-up categorization of LLM usage types, cross-labeled by the extent of student initiative these usages entail. We identify patterns in usage types and frequency across assignments, and we examine how LLM use impacts student learning, measured by performance on three midterms.

Our analysis shows a wide variation in how students used LLMs—differing in frequency, timing, and the types of support they sought. Performance analyses showed that students who used LLMs in their assignments scored lower than

non-users on the first midterm, although this gap decreased as the term progressed. Within LLM users, those who used LLMs in more than half of their assignments consistently earned lower average exam scores than those who used them less often. Similarly, students who engaged in more student-driven prompting—providing meaningful input rather than relying on the model to produce most of the content—tended to score higher, though this performance gap also narrowed over the semester. Taken together, our results suggest that, although students may benefit from guidance on how to use LLMs effectively, especially earlier on in the course, given enough time and opportunities to experience the impact of LLM usage on their exam performance, many manage to decide if and how to integrate this usage in their study process without hindering learning.

In summary, our work contributes to the growing need to understand whether and how students use LLMs, and how such usage affects learning, by providing insights in a context that is unique in two ways: first, we target the previously unexplored tasks of reading, analyzing and critiquing research papers, which require interpretation and reasoning skills beyond those involved in the most commonly investigated task of programming, problem-solving and essay writing. Second, the data used for our analysis was collected in a real course setting, where students were given complete freedom on if and how to use LLMs for their assignments. Together, these contributions broaden current understanding of how students are using LLMs in their learning and highlight the importance of investigating LLM use in ecologically valid settings where students' engagement with these tools emerges organically.

2. RELATED WORK

In this section, we review prior work on students' use of LLMs in education along two dimensions: (1) educational contexts of student LLM use, with a focus on differences across domains and instructional settings, and (2) approaches to analyzing students' LLM interactions, including both top-down and bottom-up approaches.

2.1 Educational Contexts of Student LLM Use

Prior research on students' use of LLMs in educational settings has predominantly focused on problem-solving domains, particularly programming and software development. Within this line of work, many studies examine how LLMs can be intentionally integrated into learning activities through structured instructional designs or interventions. For instance, MacNeil et al. [13] examine how specific LLM-supported interventions, such as LLM-generated code explanations, influence students' learning processes and outcomes, while Rasnayaka et al. [16] investigate the incorporation of LLMs into software development projects within project-based learning contexts. Other works explore how students interact with and perceive LLM-integrated learning environments in similar problem-solving domains [9, 20]. Although these studies provide valuable insights into the pedagogical potential of LLMs, they mainly focus on LLM use within designed or structured learning settings.

Complementing this perspective of LLM integration in educational contexts, a smaller set of studies examines how students themselves use LLMs during learning, often by analyzing student prompts or interaction logs. This work has also largely centered on problem-solving domains, where LLM use is closely tied to generating correct answers and solutions [12, 18]. As a result, existing empirical characterizations of student-initiated LLM use are largely shaped by problem-solving tasks and contexts.

Beyond problem-solving domains, there is emerging but still limited work examining LLM use in other academic domains. A few studies have begun to explore contexts such as academic writing or discussion-based learning, yet these investigations typically rely on structured forms of LLM use. For example, prior work on academic writing has analyzed student prompts within an LLM-embedded system designed to scaffold writing tasks [10], while studies in ethics education have examined discussion activities in which students were guided to use LLMs in prescribed ways [7]. Taken together, these studies illustrate early efforts to extend LLM research beyond problem-solving domains, but they also show that existing evidence remains narrow in scope. Because different academic domains require and emphasize different skills, findings derived from problem-solving contexts may not generalize to learning activities centered on other skills. This observation underscores the need for further studies of students' LLM use across a broader range of domains and academic skills.

2.2 Approaches to Analyzing Students' LLM Usage

Prior studies have employed a range of analytical approaches to examine how students use LLMs, with many relying on top-down categorization schemes. A growing body of work proposes standardized taxonomies or frameworks for analyzing human-LLM interactions or prompt strategies in more general, non-educational contexts [4, 17]. Related work in prompt engineering has also developed comprehensive categorizations of prompting techniques through reviews and conceptual frameworks [19, 6]. Building on these approaches, some educational studies apply established categorizations to student data to examine patterns of LLM use in coursework, such as analyzing student prompts according to usage categories [14].

While these top-down approaches provide useful analytical structure, they rely on predefined categories and examine how student behavior fits within them. As a result, they may overlook how students actually appropriate LLMs in practice, including uses that do not align neatly with existing taxonomies. Prior work has noted that much research on prompting and LLM interaction focuses on techniques developed or analyzed by researchers rather than on students' naturally occurring behaviors in learning contexts [18]. This gap highlights the need for complementary approaches grounded in students' observed LLM use.

Beyond top-down categorization approaches, some studies have adopted inductive or bottom-up methods that ground analysis in students' actual LLM interactions. Jelson et al.[8], for example, conduct their analysis in the context of academic writing and explicitly anchor their categorization in Flower and Hayes' cognitive model of writing [3],

organizing LLM-supported activities around the phases of planning, translating, and reviewing. Within each phase, they further inductively coded students' prompts based on the specific ways learners engaged with the LLM, allowing the final scheme to emerge from observed behaviors rather than predefined functional categories. Grande et al. [7], by contrast, take a fully inductive approach, conducting qualitative thematic analysis of LLM-supported ethics discussions to surface recurring themes without constructing an explicit taxonomy. Sawalha et al. [18] similarly use thematic analysis to identify prompting strategies in problem-solving tasks. They examine how learners use LLMs to complete quiz-style programming tasks and derive a two-level structure, distinguishing among broad prompting types and the specific strategies within them. Although these strategies vary in complexity, they are all oriented toward obtaining or refining correct answers, reflecting the goal-directed nature of problem solving.

As these examples illustrate, coding schemes naturally reflect the demands of their respective learning domains. Domains that center on interpretation, critique, and reasoning require different forms of support, and in this sense, our work parallels that of Orozco et al. [15]. They developed an emergent coding scheme grounded in students' interactions from a single research-oriented course, deriving usage types directly from observed behaviors rather than predefined taxonomies. The analysis and results presented in this paper extend this previous work by expanding the dataset to include an additional course offering from a different term. Using the coding scheme from [15] as a foundation, we iteratively refined and extended the codes as we analyzed the expanded dataset to capture the full breadth of students' LLM use, yielding a more robust characterization of students' LLM usage patterns.

3. DATA OVERVIEW

This section provides an overview of the course in which the data were collected and the composition of the dataset used for analysis.

3.1 Course Structure

Our exploratory analysis was conducted in a third-year undergraduate course offered at a public North American institution. The course's objective was to teach students research methods in the areas of Cognitive Systems, covering the skills and principles common to all forms of research, such as critical thinking and communication. As part of the course, students were assessed using 14 weekly take-home assignments and 3 in-class midterm exams distributed across the term, with the take-home assignments being graded for completion while the in-class midterm exams were graded for quality. The take-home assignments required students to read an assigned research paper on the general topic of human-AI interaction and complete two tasks:

1. **Critical Summary:** Summarize the assigned paper, focusing on the motivations of the work, the proposed solution, how the solution was evaluated, the contributions of the work, and specific aspects related to the details of the human-AI interaction.
2. **Discussion Points:** Brainstorm discussion points identifying and discussing weaknesses in the presented research, relating the research to general issues in the field, making connections with other readings, and proposing alternative approaches.

Students were permitted to use LLMs for their take-home assignments, provided they submitted a brief LLM-use report documenting the model(s) used, the prompts, and the generated output, as required by institutional policy. In contrast, the in-class midterms required students to complete the same types of tasks without any assistance. Each midterm mirrored the assignment format: students read a research paper and produced a critical summary and discussion points, as described above.

In summary, the data used for our analysis was collected as part of regular course activities and institutional requirements, including mandatory LLM-use reporting. Thus, it complies with the university's policies regarding the ownership and use of course materials for pedagogical quality assurance (Policies 81 and LR11).

3.2 Dataset Description

The data used in this paper was collected across two academic terms of the course: Term 1 included 37 undergraduate students, and Term 2 included 31, for a total of 68 students. Both terms followed the same course structure, assessment design, and LLM usage policies.

The dataset includes students' take-home assignment submissions along with their LLM-use reports (for those who used LLMs). It also includes scores from the three in-class midterm exams, which serve as evidence of students' unaided performance on tasks structurally similar to the take-home assignments.

In addition, background information about participating students was collected through a brief demographic survey. The survey asked students to report their coding ability (categorized as strong, moderate, or weak), their academic major, and their prior coursework in relevant areas (Human–Computer Interaction, Artificial Intelligence, and Machine Learning). For students in the Cognitive Systems program, majors were recorded along with their specific streams, which correspond to different disciplinary specializations (e.g., psychology, linguistics, philosophy, or computer science). Students' broader disciplinary background—such as whether they belonged to Arts or Science—was then inferred from their reported major. All collected data were anonymized prior to analysis.

4. METHODS

To determine whether data from Term 1 and Term 2 could be analyzed jointly, we compared the distributions of students' backgrounds across the two terms, focusing on self-reported coding ability and disciplinary background. Although the cohorts were not identical, their distributions were similar enough for our purposes. For coding ability, strong or moderate proficiency differed by 6.22% (83.78% in Term 1 vs. 90.00% in Term 2). For disciplinary background, the proportion of Science students differed by 10.55% (62.16%

Table 1: Categories of students' LLM usage grouped by support type.

Support Type	Category	Definition	Sample Excerpt from LLM-Use Reports
Student-driven Support	**IL**: Improving Language	Students provide their own draft text and ask the LLM to improve language (e.g., clarity, grammar).	*"Prompt Used: Here is my summary for the attached paper: [student's draft] Revise it for any grammatical issues."*
	CI: Confirming Ideas	Students propose their own ideas or drafts and ask the LLM to validate the content or to check whether the draft meets the assignment requirements.	*"Prompt Used: Does this address all the required points? [student's draft]"*
LLM-driven Support	**GI**: Generating Ideas	Students ask the LLM to suggest ideas (e.g., topics, arguments, outlines) for writing.	*"I used ChatGPT 4.0 to generate ideas for discussion points beyond what I could initially come up with after reading the paper."*
	S: Summarizing	Students ask the LLM to give an overview of the paper, which is separate from the assignment's more analytic critical summary task.	*"Prompt Used: Summarize this paper."*
	GA: Generating Answers	Students ask the LLM to generate an answer or text from scratch (discussion points or critical summary).	*"In the prompt, I passed the file of the paper and the document of the discussion document [assignment format] and asked it to complete it."*
Comprehension Support	**IE**: Information Extraction	Students ask the LLM to extract specific information from a paper.	*"Asked GPT to help with finding the mitigating solution against the potential usability threats.'*
	CC: Clarifying Concepts	Students ask the LLM for further explanation to deepen understanding of certain concepts.	*"Prompt Used: What's the difference between formula 1 and formula 2 in the paper?"*

vs. 51.61%), with the remaining percentages falling into the Arts category. Given these broadly comparable patterns, we analyzed the two cohorts together in subsequent analyses.

4.1 Coding Scheme for LLM Usage

A bottom-up coding scheme was used to characterize students' LLM usage. The analysis began with the coding framework introduced in earlier work [15], which identified seven usage categories: *Improving Language*, *Paragraph from Bullets*, *Clarifying Concepts*, *Confirming Ideas*, *Generating Ideas*, *Summarizing*, and *Generating Answers*. This framework served as an initial guide and was iteratively refined while analyzing the expanded two-term dataset to better capture the full range of usage behaviors observed.

Each submission was coded individually, and multiple categories were assigned whenever a student's prompts reflected more than one form of usage, such as when they engaged in several distinct interactions within the same submission. Using the existing categorization [15] as a starting point, two authors independently coded all LLM-use reports. Inter-rater reliability, assessed with Krippendorff's alpha, which is appropriate for nominal data with multiple labels per entry, indicated low agreement beyond chance across all categories (α range = -.01 to .03). This low reliability suggested that several category definitions overlapped or required clearer differentiation. The two authors then met to review the coded data, discuss sources of disagreement, and refine the categorization by clarifying definitions and determining where categories should be merged or further distinguished. Following this refinement process, the authors iteratively discussed and reconciled remaining disagreements until consensus was reached on all coded instances, resulting in a finalized coding scheme and dataset used for analysis.

The refinement process led to modifications of the existing categories as follows: first, we consolidated "Paragraph from Bullet Points" into "Improving Language." In the initial categorization, "Paragraph from Bullet Points" captured submissions in which students provided bullet-point inputs and asked the LLM to convert them into a paragraph. However, this process inherently involved improving wording, structure, or clarity, resulting in substantial conceptual overlap with the "Improving Language" category. Moreover, a closer examination of these submissions revealed considerable variability in the level of detail provided by students, ranging from brief keyword-style bullet points to full sentences or paragraph-length inputs. This inconsistency, combined with the significant overlap in function, motivated the decision to merge "Paragraph from Bullet Points" into the broader "Improving Language" category.

Second, refinements to the "Clarifying Concepts" category led to the creation of a new category, "Information Extraction." Initially, queries that asked the LLM to locate specific information within the assigned paper were grouped under "Clarifying Concepts" since that category broadly covered student questions about course material. However, closer analysis showed that these queries were not aimed at deepening conceptual understanding but at retrieving specific information from the paper—such as checking whether particular details appeared in the text rather than interpreting the

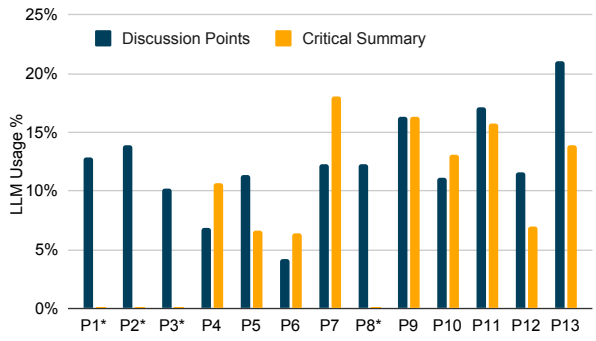

Figure 1: LLM usage rates for discussion points and critical summary tasks per paper. Asterisks indicate assignments with discussion points only.

underlying concepts. This distinction led to the separation of the two categories, where questions that sought conceptual clarification without explicitly requesting information from the paper were retained under "Clarifying Concepts," whereas queries that involved searching for text or data explicitly stated in the paper were classified as "Information Extraction."

This process resulted in our final set of seven categories—Improving Language, Confirming Ideas, Generating Ideas, Summarizing, Generating Answers, Information Extraction, and Clarifying Concepts. Definitions of each category and corresponding sample excerpts from the LLM-use reports are presented in Table 1. The table also shows that the categories are organized into three higher-level types of support types based on the role the LLM played in the student's work:

- **Student-driven Support**: cases in which students provided initial ideas or drafts and used the LLM for feedback, refinement, or confirmation (includes Improving Language and Confirming Ideas)
- **LLM-driven Support**: cases in which students used the LLM to generate content from scratch with minimal prior input (includes Generating Ideas, Summarizing, and Generating Answers)
- **Comprehension Support**: uses of LLMs to help understand the assigned paper or related concepts (includes Information Extraction and Clarifying Concepts)

4.2 Analysis Procedure

Analyses were conducted at two complementary levels. At the submission level, LLM usage behaviors were examined for each individual take-home assignment, with submissions coded into one or more usage categories based on the coding scheme described above. Category frequencies and usage patterns were then summarized across all submissions.

At the student level, LLM usage data were aggregated across each student's submissions and compared with their in-class midterm exam scores to examine how patterns of LLM use related to learning. This analysis considered both the extent of students' LLM use and the types of support they sought.

We employed descriptive statistics and group-based comparisons to examine overall usage trends, associations between LLM usage and learning, and differences across LLM support types. Analyses focused on identifying patterns of association rather than making causal claims.

5. RESULTS

In this section, we present our findings on how students used LLMs throughout the course and how these usage patterns relate to midterm exam performance, considering both the level of LLM use and differences in LLM usage types.

5.1 Students' LLM Usage Trends

We organize our analysis of students' engagement with LLM into two parts: (1) whether and how frequently students used LLMs across assignments over time, and (2) how students used LLMs in terms of the functional purposes captured in our coding scheme.

23 out of 68 students (34%) reported using LLMs in at least one submission. On average, students used LLMs in 12% of discussion point submissions and 11% of critical summary submissions. Students reported using a range of LLM tools, including ChatGPT (e.g., GPT-3.5, GPT-4, and GPT-4o), NotebookLM, and Claude models. To see how these rates varied for each assignment, Figure 1 shows the percentage of students who used LLMs for the two tasks, with papers (P1–P13) arranged chronologically from left to right on the x-axis. Note that for some papers, students had to submit only discussion points, no summaries (P1, P2, P3, and P8; indicated with an asterisk in Figure 1). The figure illustrates that LLM usage varied across assignments and tasks: for some papers, students used LLMs more for discussion points, whereas for others, usage was higher for the critical summary. A notable trend is the increase in LLM usage for later assignments, particularly for the discussion points task, suggesting that students may have grown more comfortable integrating LLMs into their workflow as the course progressed. While actual usage may be slightly higher due to potential underreporting (e.g., students neglecting to declare LLM use), it is unlikely that the true usage rate differs substantially, as students were explicitly permitted to use AI tools without penalty provided such use was disclosed.

Figure 2 provides a more detailed view of how each of the 23 students who used LLMs at least once (SN on the y-axis) engaged with LLMs for each assignment (P1 through P13 on the x-axis). The papers (P1–P13) are shown in chronological order from left to right. Submissions for each paper (PN) are separated in into discussion points (PN DP) and critical summary (PN CS). The types of LLM use categorized for each submission are indicated in each cell by the corresponding code (see Table 1). Cells contain usage codes when the student used an LLM for that task, appear in yellow when the student reported no LLM use, and are crossed out when the assignment was not submitted. Two vertical lines in the middle of the figure mark the timing of Midterm 1 and Midterm 2, and Midterm 3 occurred after the final assignment. Students are then ordered by their overall frequency

Figure 2: Temporal visualization of reported LLM use across assignments.

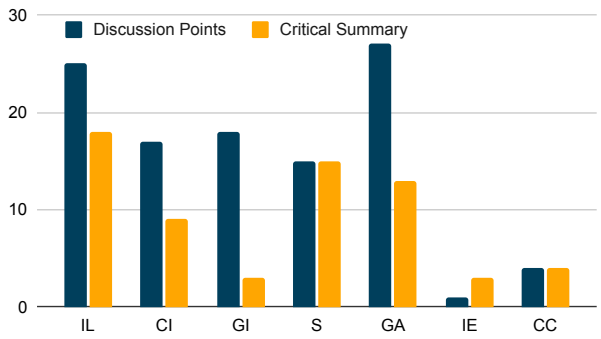

Figure 3: Counts for each LLM usage category for discussion points and critical summary.

of LLM use, with the most frequent users appearing at the bottom and the least frequent at the top. Because some students did not submit every assignment, usage frequency is computed as the number of assignments in which they used an LLM divided by the number they submitted. Notably, S63 appears at the very bottom: although their use of LLMs may look sparse visually, this is because they submitted only 3 of the 13 assignments—but used LLMs for all three—resulting in a 100% usage rate.

The visualization shows a distinct cluster of students who had a much higher usage frequency toward the bottom. Looking at the actual frequencies, a clear breakpoint emerges at S62: students above S62 used LLMs in only 5–33% of their submissions, while those from S62 downward used them in 50–100% of their work. This pattern provides a natural division into two groups, with 7 students using LLMs in at least half of their submitted assessments and 16 students whose usage remained below that threshold. In the rest of this analysis, we will indicate the two groups as *High-Reliance* and *Low-Reliance*, respectively.

These two groups showed different trend of LLM usage over time. Students in the Low-Reliance group showed more concentrated usage early in the term, with an average of three students using LLMs per assignment before Midterm 1. After Midterm 2, this average fell to one, indicating that students in this group not only rely on LLMs only lightly, but they reduced their usage as they grew more comfortable with the assignment tasks over time. In contrast, within the High-Reliance group, several students (S62, S34, S61, S59) used LLMs consistently throughout the term while others (S2, S38) shifted into heavier use partway through the term. S2 refrained from using LLMs until after Midterm 1, at which point they started using them in every subsequent submissions. Similarly, S38 began to use LLMs at the halfway point of the term, and then continues to use it for every submission until the end of the course. These varied trajectories within the High-Reliance group suggest that these two students may have adjusted their reliance on LLMs as they grew more familiar with the course structure and their workflow for using them, resulting in increased use later in the term when they felt such usage would no longer hinder their ability to perform the assignment tasks on their own during the midterm.

We next examine how LLMs were used in terms of usage category. Figure 3 presents overall counts for each LLM usage category grouped by assignment tasks (Discussion Points vs Critical Summary). As the figure shows, Summarizing (S) and Clarifying Concepts (CC) were used equally for the two tasks, which makes sense since both these usages help understand the content of the paper, which is needed for both tasks. Information Extraction (IE) is used more for critical summaries, which also makes sense since writing the critical summary is more directly related to finding specific information in the paper. All the other usages are higher for discussion points, showing that for this activity, which is more open-ended and requires going beyond the content of the paper, students needed more help on Improving Language (IL), Confirming Ideas (CI), Generating Ideas (GI) and Generating Answers (GA).

Figure 4 shows stacked bar graphs indicating, for each usage category, the proportion of individual students in the High-Reliance group who used it. Figure 5 shows the same information for students in the Low-Reliance group.

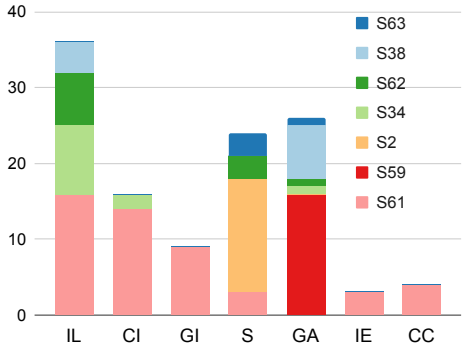

Figure 4: Counts for each LLM usage category, with stacked bars showing the proportion of individual students in the High-Reliance group.

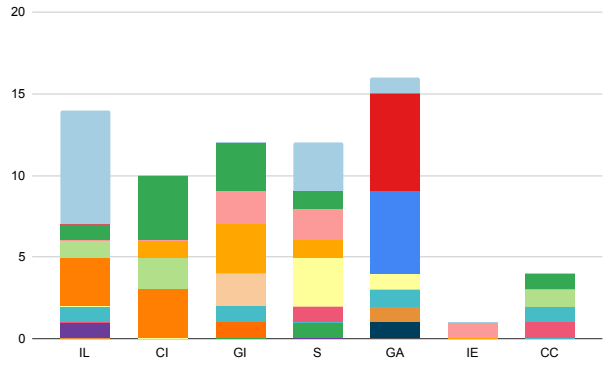

Figure 5: Counts for each LLM usage category, with stacked bars showing the proportion of individual students in the Low-Reliance group. Each color represents a different student.

As seen in Figure 4, in the High-Reliance group, three categories (Generating Ideas (GI), Information Extraction (IE), and Clarifying Concepts (CC)) were used only by one student, S61. This student used all the categories except for Generating Answers (GA), indicating that, although the student relied heavily on LLMs, they never used them to generate the assignment from scratch. Notably, S61's midterm scores steadily increased across the term (69% to 72% to 79%), illustrating that extensive LLM use—when focused on forms of support other than full answer generation—can coexist with, and may even accompany, improved performance. By comparison, S59 used LLMs solely for Generating Answers (GA), and S63 used only Generating Answers (GA) and Summarizing (S), both examples of LLM-driven support. Finally, S2 used only Summarizing (S), and their performance provides a clear illustration of the potential consequences of this pattern: their midterm scores declined consistently—from 65% to 48% to 38%. After Midterm 1, S2 appears to have increasingly relied on LLM-generated summaries rather than engaging with the full readings, which may have weakened their ability to process new material during the exams. The remaining students (S62, S38 and S34) spread their LLM usage over both student-driven and LLM-driven categories.

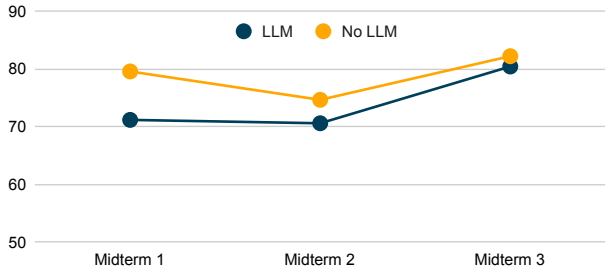

Figure 6: Comparisons of midterm exam scores between students who used LLMs in assignments (*LLM*) and those who did not (*No LLM*).

Figure 5 shows that, in the Low-Reliance group, each usage type was used by at least four different students aside from Information Extraction, indicating a relatively even distribution of usage across categories. This contrasts with the High-Reliance group, where certain categories are dominated by only a few students. Notably, even within the Low-Reliance group, Generating Answers (GA) was the most frequently used category. Two students in particular—S44 (red; second segment from the top in the GA bar) and S23 (blue; third segment from the top in the GA bar)—used Generating Answers (GA) more than any other category. As Figure 2 illustrates, both students tended to rely on Generating Answers (GA) more heavily toward the end of the term. Interestingly, S44 and S23 showed strikingly similar performance trajectories across the three midterms. Both improved substantially from Midterm 1 to Midterm 2 (S44: 54% to 82%; S23: 65% to 84%) but experienced a decline on Midterm 3 (S44: 78%; S23: 76%). This parallel trend suggests that increased reliance on Generating Answers (GA) later in the course did not necessarily prevent performance gains, but may also not have sustained them through the final assessment.

5.2 Impact of LLM Usage on Midterm Performance

5.2.1 *Performance Differences by Level of LLM Use*

We examined how students' use of LLMs in take-home assignments impacts their performance in midterm exam performance. For each midterm, we distinguished between students who had used LLMs in any prior assignment and those who had not. Because students adopted LLMs at different times during the term, group sizes varied across midterms. For example, S2 did not use LLMs before Midterm 1 but began doing so between Midterms 1 and 2, and was therefore treated as an LLM user for Midterm 2 and Midterm 3, but not Midterm 1. For Midterm 1, three students were excluded from the analysis: two were absent, and one experienced technical issues at the start of the exam that reduced their available exam time by half. Midterm 2 had one absent student, while Midterm 3 had three students absent.

We first compared midterm exam scores between students who reported using LLMs and those who did not. Figure 6 shows line graphs of the averages over the 3 midterms, for the students who did use LLMs (*LLM*) and those who did

Table 2: Comparisons of midterm exam scores between students who used LLMs in coursework (*LLM*) and those who did not (*No LLM*). Here, M denotes Midterm.

M	Condition	N	M	SD	t	df	p	d
M1	No LLM	44	79.60	13.15	-2.5	41.8	**0.016***	-0.65
	LLM	21	71.20	12.36				
M2	No LLM	44	74.68	11.52	-1.5	52.0	0.133	-0.37
	LLM	23	70.62	9.69				
M3	No LLM	42	82.24	9.04	-0.7	39.6	0.499	-0.19
	LLM	23	80.46	10.60				

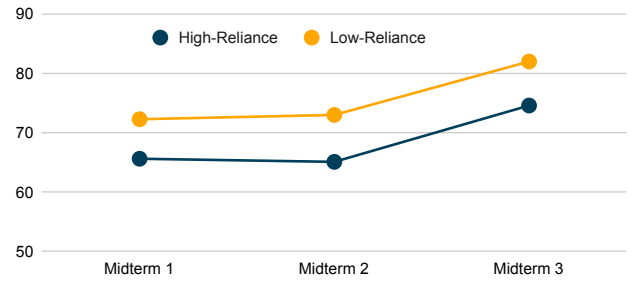

Figure 7: Comparisons of midterm exam scores between students in the High-Reliance and Low-Reliance groups.

not (*No LLM*). It shows that students in the No LLM group scored higher on average than the LLM group, although this gap narrowed as the term progressed. In Midterm 2, this is due to a decrease in performance for the No LLM group, whereas the performance of the LLM group remains similar to Midterm 1. In Midterm 3 both groups improve. A possible explanation is that, as students became more familiar with the processes entailed in the exam tasks, the impact of LLM usage on midterm performance may have diminished. Statistical tests and detailed score values are provided in Table 2, showing a statistically significant difference in performance between the LLM and No LLM groups for Midterm 1, with a high effect value.

We further investigate the impact of LLM usage on midterm exams by comparing the performance of High-Reliance and Low-Reliance students within the LLM group. Because the group sizes were highly imbalanced (seven vs sixteen), we did not conduct statistical tests; instead, we interpret the descriptive trends shown in Figure 7, which compares midterm exam scores between the two reliance groups across the three midterms. On average, Low-Reliance group consistently outperformed the High-Reliance group across all three midterms, with a stable performance gap of approximately 7-8% throughout the term. As a matter of fact, the Low-Reliance group performed similarly to the No LLM group, with a performance gap of just 3%.

5.2.2 *Performance Differences by LLM Usage Types*

Among students who reported using LLMs, we further examined whether their performances differed depending on the types of LLM support they relied on. Because individual students often engaged in multiple forms of LLM use

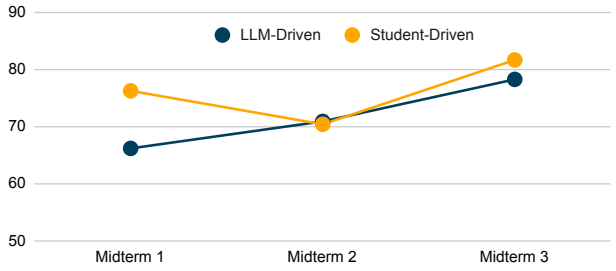

Figure 8: Comparisons of midterm exam scores between LLM-driven support group and Student-driven support group

across assignments, we conducted this analysis by classifying each student based on the three LLM support types they used most frequently among the three listed in Table 1. Those who most frequently used usage types categorized as student-driven support were assigned to the *student-driven support* group; those who most frequently used LLM usage types that are LLM-driven support were assigned to the *LLM-driven support* group; and those who most frequently used LLM usage types that are comprehension support were assigned to the *comprehension support* group. Based on this criterion, 23 students were included in the analysis: 14 were classified as LLM-driven support group and 7 as student-driven, with 2 students left unclassified due to equal frequencies across support types.

We then compared midterm exam scores between students whose LLM use was classified as LLM-driven and those classified as student-driven. Because the group sizes were highly imbalanced—similar to the comparison between the High-Reliance and Low-Reliance groups—we did not conduct statistical tests and instead observed the trends in the average midterm exam scores shown in Figure 8. As the figure illustrates, students in the student-driven group scored higher on Midterm 1, but the performance of the two groups converged in subsequent midterms. This pattern suggests that the type of support students sought—reflecting differences in how much effort they invested in contributing substantive work themselves—impacted their midterm performance early in the course, but that this effect may have diminished as students became more familiar with the course content and exam structure, similar to the comparison between LLM and No LLM groups.

6. DISCUSSION

In this section, we summarize our results regarding students' LLM usage and its impact on learning, as measured by midterm performance.

We found that only a minority of students (23 out of 68; 34%) used LLMs for the course assignments. Among these students, most (16 students) used LLMs lightly, relying on them for approximately 5–33% of their submissions (Low-Reliance group). Their LLM use also tended to be concentrated earlier in the course, primarily before the first midterm. This pattern suggests that as these students became more confident with the course material and the exam

structure, the perceived benefits of using LLMs may have decreased, reducing their incentive to rely on them. The remaining seven students used LLMs more heavily (i.e., in more than 50% of their submissions; High-Reliance group), either by using them consistently across assignments or by increasing their usage later in the course.

We observed a trend in which Low-Reliance students performed between 7% and 8% better on the three midterms than High-Reliance students, suggesting that the amount of LLM usage may be associated with differences in test performance in this context.

Our results also showed that students used LLMs in qualitatively different ways. Some forms of usage required substantial work and input from the student (student-driven support), while others relied more heavily on the LLM to generate content (LLM-driven support). We observed a trend in which students with a higher frequency of student-driven usage performed better on the midterms than students with a higher frequency of LLM-driven usage, particularly on the first midterm (a 10% difference). This finding suggests that the type of LLM usage may be another factor influencing test performance in this context.

Overall, we found a statistically significant difference in performance on the first midterm between students who reported using LLMs on the assignments preceding this exam and students who reported no LLM use, with the latter group performing better with a large effect size. This difference decreased for the subsequent two midterms and, notably, the LLM-using group improved by approximately 10% from the first midterm to the last.

Thus, although the type and amount of LLM use may have negatively affected student learning early on in the course, as the course progressed, most students appeared to calibrate their LLM use to better complement their learning processes. These findings provide encouraging evidence that the use of LLMs does not necessarily hinder learning, which is a major concern expressed within the educational community. Our results further suggest that many students are able to leverage LLMs constructively even without explicit guidance, given sufficient opportunity and time to experiment with their use. This offers initial evidence against the common concern that students will inevitably over-rely on LLMs in ways that undermine learning if left to their own devices. That said, our findings also indicate that providing guidance on effective LLM usage early in the course may help accelerate appropriate and productive adoption.

It should be noted, however, that in the course addressed in this paper, students could directly experience the impact of their LLM usage on performance through the midterms, as these assessments involved the same types of tasks as the assignments. In instructional settings where the connection between assignments and in-class exams is less explicit—and where the consequences of LLM use for exam performance are therefore less immediately observable—additional instructional scaffolding, feedback, or explicit guidance may be necessary to support effective and learning-oriented use of LLMs.

7. CONCLUSION

This work examined how students used LLMs in a research-oriented course, revealing diverse patterns of engagement and how these behaviors related to performance on an independently completed midterm exam. Our analyses showed meaningful variation in when students chose to use LLMs, the types of support they sought, and the amount of effort they contributed themselves, underscoring that LLM use is far from uniform. Overall, the results offer an encouraging view: LLM use is not inherently detrimental, and several students demonstrated that, when used constructively, these tools can support—rather than hinder—learning.

Future work can build on this study in several important ways. First, although our analysis revealed clear patterns, the dataset—particularly within certain subgroups—was relatively small, meaning that some observations should be interpreted as trends rather than definitive effects. Replicating and extending these analyses with larger dataset would help establish the robustness and generalizability of our findings. Second, future work should also explore additional factors that may shape students' engagement with LLMs. For example, prior research highlights the role of AI literacy in influencing how students use these tools [10], suggesting that students' competencies, confidence, and prior experience with AI may meaningfully interact with their usage patterns. Other individual or contextual factors—such as study strategies or prior familiarity with research-based coursework—may also play a role and warrant further investigation.

Building on our findings summarized in Section 6, we examined naturally occurring LLM usage behaviors and demonstrated how these categories relate to students' ability to perform in a new domain. By qualitatively analyzing the students' LLM-use reports to interpret their intentions and combining this with performance outcomes, we show that the manner in which students use LLMs—not merely the frequency of use—plays a meaningful role in learning. In summary, our work advances understanding of whether and how students use LLMs, and how such usage affects learning, by examining LLM engagement in a cognitively demanding, interpretation-focused context and in an authentic course setting where usage patterns emerged organically. Together, these contributions represent one step toward a more comprehensive account of student–LLM interaction across different learning domains and underscore the importance of studying LLM use in ecologically valid environments.

ABSTRACT

Accurate and unambiguous guidelines are critical for large language model (LLM) based graders, yet manually crafting these prompts is often sub-optimal as LLMs can misinterpret expert guidelines or lack necessary domain specificity. Consequently, the field has moved toward automated prompt optimization to refine grading guidelines without the burden of manual trial and error. However, existing frameworks typically aggregate independent and unstructured error samples into a single update step, resulting in "rule dilution" where conflicting constraints weaken the model's grading logic. To address these limitations, we introduce **C**onfusion-**A**ware **R**ubric **O**ptimization (**CARO**), a novel framework that enhances accuracy and computational efficiency by structurally separating error signals. CARO leverages the confusion matrix to decompose monolithic error signals into distinct modes, allowing for the diagnosis and repair of specific misclassification patterns individually. By synthesizing targeted "fixing patches" for dominant error modes and employing a diversity-aware selection mechanism, the framework prevents guidance conflict and eliminates the need for resource-heavy nested refinement loops. Empirical evaluations on teacher education and STEM datasets demonstrate that CARO significantly outperforms existing SOTA methods. These results suggest that replacing mixed-error aggregation with surgical, mode-specific repair yields robust improvements in automated assessment scalability and precision.

1. INTRODUCTION

The rapid shift toward personalized and competency-based learning has placed unprecedented challenges for traditional assessment frameworks. As personalized learning relies on understanding the specific needs for each learner, it necessitates high-quality formative assessment. In modern pedagogy, providing frequent and high-quality assessment feedback on students' open-ended work is essential for diagnosing misconceptions and fostering deep conceptual understanding [2, 13, 25]. Yet these benefits are hard to deliver at scale. Constructed-response tasks, such as short answers or explanations, capture students' reasoning more directly than multiple-choice formats, but they are substantially more time-consuming to assign and evaluate. Furthermore, they can exhibit nontrivial scorer disagreement even under rubric-based evaluation [19]. Notably, this disagreement often stems from the linguistic diversity and variability inherent in student answers. This "grading bottleneck" is reflected in teachers' reported workloads, where scoring and correcting student work consumes a sizable share of working time across education systems [22]. As a result, educational practice often trades off authenticity for scalability by reducing the use of open-ended items or returning feedback after long delays. These compromises weaken the instructional value of assessment and motivate automated grading as a way to preserve the pedagogical benefits of constructed responses without prohibitive cost or latency [1, 18].

Traditional methods of automated grading primarily relied on hand-crafted features, such as keyword matching, latent semantic analysis (LSA), or surface-level linguistic metrics [11]. These approaches requires task-specific feature engineering and fails to capture the semantic nuances of student reasoning, resulting in rigid evaluations that often penalize creative but correct answers [10]. The advent of deep learning introduced fine-tuning techniques using encoder-based models like BERT, which significantly improved semantic understanding and scoring accuracy [9, 20]. However, these models require extensive labeled datasets for training before applicable to the new tasks, making them impractical for dynamic classroom environments where assignments change frequently. Recent advancements demonstrate

that large language models (LLMs) overcome this data barrier. Unlike their predecessors, LLMs can leverage zero-shot and few-shot capabilities (i.e., they can operate effectively with little to no labeled data) to grade open-ended student responses with performance approaching human-to-human agreement levels [4]. Despite this promise, the transition from human grading to LLM-driven assessment is fraught with technical hurdles. In particular, reliability is heavily contingent on the quality of the grading prompt, with the instructions and rubric operationalization constraining the model's decision-making [4, 14]. Simply treating a human rubric as an instruction for an LLM is often sub-optimal; human rubrics, while intuitive for expert educators, often contain linguistic ambiguities that misalign with the causal reasoning of an LLM. This "alignment gap" necessitates extensive prompt engineering, a process that is often manual and driven by iterative trial and error, making it difficult to scale [6, 28]. Consequently, the field has moved toward *automated prompt optimization* (APO), where algorithms iteratively refine instructions based on quantitative performance feedback [29, 6].

While state-of-the-art frameworks like GradeOpt [6] leverage reflective optimization to diagnose errors, they are limited by their naive treatment of the error signal, which incurs substantial computational overhead when searching over large prompt spaces. Specifically, these methods aggregate heterogeneous error samples into a composite feedback signal, combining distinct failure types such as hallucination, excessive strictness, and rubric misunderstanding into a single optimization step without separation. This confounding of error types leads to *rule dilution*. That is, by attempting to address a mixture of conflicting signals simultaneously, the optimizer generates generalized, weak instructions that fail to enforce clear decision boundaries. Consequently, to find even a marginally improved prompt, these methods rely on resource-heavy exploration, generating and evaluating large pools of candidates.

To address this, we introduce **CARO** (**C**onfusion-**A**ware **R**ubric for **O**ptimization), a framework that achieves superior accuracy and computational efficiency by structurally separating error signals. We observe that grading errors are not random mixtures, but structured clusters. CARO leverages the confusion matrix to decompose the monolithic error signal into distinct **error modes**, eliminating the inefficiency of trying to address conflicting error types simultaneously. Specifically, CARO targets the single **dominant error mode** at each step (e.g., a specific tendency to confuse a score of 0 with 1), transforming the optimization into a structured **diagnosis-and-repair** pipeline. By isolating a single, clear failure pattern, CARO generates targeted "rule patches" that are specific and highly effective. Contributing to its precision, CARO produces robust prompts with significantly fewer iterations and lower token usages compared to the existing APO baselines. Our empirical results confirm that CARO significantly outperforms these frameworks across multiple datasets while utilizing the same cost-effective backbone (`GPT-4o-mini`[1]).

2. RELATED WORK

Automated short-answer grading (ASAG). Early ASAG systems relied on hand-crafted lexical features and latent semantic analysis to predict scores [21]. The field later transitioned to neural architectures, utilizing recurrent models and Transformer encoders trained on graded corpora to capture deeper semantic dependencies [26, 12]. Despite their improved accuracy, these supervised pipelines require extensive labeled data for each specific question and lack the interpretability of rubric-based assessment. This limitation motivated the shift toward Large Language Models (LLMs), which offer zero-shot flexibility and the capacity to generate human-readable feedback alongside scores.

LLM-based grading and prompt optimization. Recent studies demonstrate that LLMs can achieve high agreement with human graders, though performance remains heavily dependent on rubric specificity and prompt design [14, 3]. While frameworks like RAG can improve domain grounding [5], the challenge of manual tuning has accelerated the adoption of Automatic Prompt Optimization (APO). APO treats instructions as trainable parameters, ranging from iterative meta-optimization in OPRO and DSPy [27, 16] to the "natural-language gradients" used in ProTeGi [23]. In the educational domain, GradeOpt applies these principles to refine grading guidelines via self-reflection [6]. However, these systems generally aggregate heterogeneous errors into a single feedback signal, often obscuring the distinct failure patterns critical for precise assessment.

3. PROBLEM FORMULATION

We formalize the task of automated rubric optimization as a discrete search problem over the space of natural language instructions. Unlike fine-tuning LLM parameters, which requires extensive labeled data and computational resources, we focus on optimizing the rubric prompt in the text space. This approach leverages the in-context learning capability of pre-trained LLMs while maintaining interpretability so that graders can inspect and validate the optimized rubric before deployment. Let $\mathcal{D} = \{(x_n, y_n)\}_{n=1}^{N}$ be a dataset of student responses x and ground-truth scores $y \in \mathcal{Y}$, where $\mathcal{Y} = \{0, 1, \ldots, K-1\}$ represents an ordinal grading scale. An LLM-based grader can be defined as a function f_θ that estimates the probability $P_\theta(y|x, \mathcal{P})$ of a score y given a response x and a rubric prompt $\mathcal{P}$. The predicted score is obtained as $\hat{y} = \arg\max_{y \in \mathcal{Y}} P_\theta(y|x, \mathcal{P})$. The objective of *Automated Prompt Optimization (APO)* is to identify an optimal prompt $\mathcal{P}^*$ that maximizes a performance metric $\mathcal{M}$ (e.g., classification accuracy or quadratic weighted kappa) over a validation dataset:

$$\mathcal{P}^* = \arg\max_{\mathcal{P} \in \mathcal{S}} \mathcal{M}\big(\{\hat{y}_n, y_n\}_{n=1}^{N}\big) \tag{1}$$

where $\mathcal{S}$ denotes the discrete search space of candidate prompts. Since the optimization targets the natural language prompt directly to ensure the rubric remains human-readable, standard differentiable optimization methods applicable to continuous parameters are not viable. Instead, APO methods approximate the gradient by generating textual feedback g based on the discrepancy between predicted scores $\hat{y}$ and true scores y, effectively performing a semantic descent step

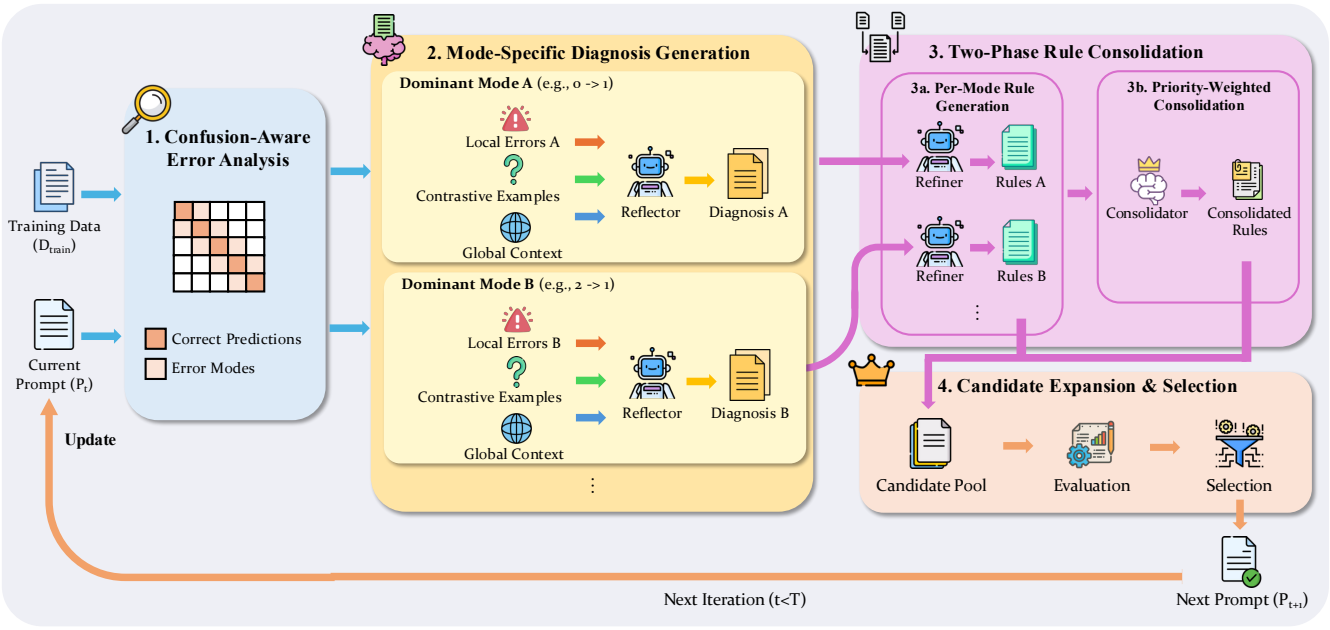

Figure 1: Framework of the CARO algorithm.

$\mathcal{P}_{t+1} \leftarrow \text{Update}(\mathcal{P}_t, g)$.

The goal of our work is to address the structural inefficiency problem of the feedback signal g when generated from aggregated error data. In the context of ordinal grading, errors are not uniform; they constitute distinct directional error modes captured by the confusion matrix $\mathbf{C}$, where an entry C_{ij} represents the frequency of true class i being misclassified as j. Existing APO frameworks typically aggregate a batch of heterogeneous error samples by mixing instances of $i \to j$ confusion with $k \to l$ confusion to generate a single, composite feedback signal. We define this aggregation as the source of *rule dilution*. By exposing multiple error modes simultaneously, such methods require the optimizer model to solve a multi-objective task that demands high reasoning capacity to disentangle competing patterns. To address this challenge, we adopt a multi-agent decomposition strategy that separates the complex task into focused sub-problems: (1) a *Mode-Specific Reflector* that analyzes each confusion cell (i, j) independently to generate targeted feedback, and (2) a *Consolidator* that synthesizes per-mode refinements into a coherent, non-redundant rule set while maintaining global consistency.

Furthermore, this optimization landscape is characterized by high inter-dependency between grading criteria, leading to *mode interference*. Addressing a specific error mode C_{ij} in isolation can act as a perturbation to the decision boundary between classes i and j. Due to the semantic continuity of the rubric, this perturbation often propagates to adjacent boundaries, inadvertently increasing the error rate in a connected mode C_{jk} or C_{ji}. This phenomenon creates a non-monotonic optimization trajectory where the reduction of one error type systematically amplifies another. Consequently, the optimization objective shifts from merely minimizing the total error count to identifying a structured sequence of rule refinements that effectively *decomposes* the confusion matrix $\mathbf{C}$ without causing regression in previously stabilized modes. Our framework addresses this via a decomposition strategy that first generates mode-specific rules with global context awareness, then consolidating them with explicit priority ordering and cross-mode safety checks.

4. METHOD

We propose CARO (**C**onfusion-**A**ware **R**ubric for **O**ptimization), a framework designed to overcome the limitations of aggregating feedback in automated rubric optimization. Existing methods often suffer from rule dilution, where conflicting error signals lead to vague instructions. To address this, CARO structurally decomposes the optimization problem using confusion matrices, treating grading errors not as random noise but as distinct, diagnosable modes. Our approach operates in three iterative phases: confusion-aware error analysis, mode-specific gradient generation, and priority-weighted rule consolidation.

4.1 Framework Overview

Figure 1 illustrates the complete CARO pipeline. To efficiently navigate the extensive search space of natural language prompts, CARO employs an iterative, minibatch-based optimization loop. In each iteration t, rather than evaluating on the entire training set, which is computationally expensive and may obscure minority error patterns, we sample a focused subset of data (a *minibatch*) to estimate the current rubric's performance. This iterative design allows the framework to progressively refine the rubric, addressing the most prominent error modes in early rounds before fine-tuning for edge cases.

The framework operates as a closed-loop optimization system with four interconnected components. **Components 1–3** form the core optimization loop within a single round:

(1) Confusion-Aware Error Analysis grades the minibatch and extracts structured error patterns; (2) Mode-Specific Gradient Generation produces targeted feedback for each confusion cell using a Reflector LLM; and (3) Two-Phase Rule Consolidation synthesizes per-mode rules into a unified rubric. These three components pass information sequentially within each optimization round. **Component 4** (Candidate Selection and Sampling) operates at a different granularity as it governs the *inter-round* dynamics. It acts as a bridge between iterations by determining which candidate prompts survive to round $t+1$ and constructing the specific training minibatch that will be used to evaluate it. This separation reflects the algorithmic structure: Components 1–3 generate candidate prompts within a single round, while Component 4 decides *which* candidates propagate across rounds and *what data* they will be evaluated on next. The dashed connection in the figure indicates this temporal decoupling.

The complete procedure is summarized in Algorithm 1. Given an initial rubric prompt $\mathcal{P}_0$, a training dataset $\mathcal{D}_{\text{train}}$, and a LLM predictor f_θ, our objective is to iteratively optimize the prompt to minimize classification errors while ensuring stability across different score categories. The optimization process functions as a directed search. At each iteration t, we first evaluate the current prompt on a minibatch to generate a confusion matrix $\mathbf{C}^{(t)}$ (Algorithm 1, lines 4–7). From this matrix, we identify the top-K error modes, denoted as $\mathcal{M} = \{(i_1, j_1), \ldots, (i_K, j_K)\}$, ranked by frequency (line 8). Unlike standard methods that aggregate these errors, CARO generates distinct gradients for each mode (lines 10–16), which are subsequently consolidated into coherent rule updates (lines 18–23). This cycle repeats until convergence or a maximum step count T is reached.

4.2 Confusion-Aware Error Analysis

The diagnostic phase begins by explicitly evaluating the current rubric $\mathcal{P}^{(t)}$ on the sampled minibatch to generate a set of predictions and their corresponding reasoning traces. By comparing these predictions $\hat{y}$ against ground truth y, we construct a confusion matrix $\mathbf{C}^{(t)}$ (lines 4–7). Based on this performance data, we construct a comprehensive context for the optimizer. For each identified confusion mode $(i, j) \in \mathcal{M}$, we assemble three distinct types of information to ground the model's reasoning. First, we extract **local error context**. This consists of specific examples $\mathcal{E}_{i\to j} = \{(x, y, \hat{y}, r)\}$ where the true label y is i, but the model predicted $\hat{y} = j$, accompanied by the model's reasoning trace r (line 12). Second, to establish clear decision boundaries, we sample *contrastive correct examples*. These are instances correctly classified as i or j but which exhibit high model uncertainty (line 13). We quantify this uncertainty using a misconfidence score [6]:

$$\text{misconf}(x) = \begin{cases} -\log P_\theta(\hat{y}|x) & \text{if } \hat{y} = y \\ \left| \frac{\log P_\theta(\hat{y}|x)}{\log P_\theta(y|x)} \right| & \text{if } \hat{y} \neq y \end{cases} \tag{2}$$

where $P_\theta(c|x)$ denotes the predicted probability for class c. High misconfidence in correct predictions signals boundary cases that provide high-value discriminative signals. Finally, we provide **global context** via the full confusion matrix summary, GlobalContext($\mathbf{C}$). This summary includes the error distribution across all classes, ensuring that the optimizer remains aware of the global performance landscape and avoids overfitting to a single error type at the expense of others.

Algorithm 1 CARO: Confusion-Aware Rubric Optimization

Require: Initial rubric prompt $\mathcal{P}_0$, training data $\mathcal{D}_{\text{train}}$, LLM predictor f_θ, rounds T, beam size B, top-K modes, diversity weight λ
Ensure: Optimized rubric prompt $\mathcal{P}^*$
1: $\mathcal{P}^{(0)} \leftarrow \{\mathcal{P}_0\}$ {Initialize candidate set}
2: **for** $t = 1$ **to** T **do**
3: `// 1. Confusion-Aware Error Analysis`
4: Minibatch$^{(t)} \leftarrow$ SBERTSample(TopMisconf$^{(t-1)}, \mathcal{D}_{\text{train}}$)
5: **for** each $\mathcal{P} \in \mathcal{P}^{(t-1)}$ **do**
6: Evaluate $\mathcal{P}$ on Minibatch$^{(t)}$ to obtain $\mathbf{C}^{(t)}_{\mathcal{P}}$
7: **end for**
8: $\mathcal{M} \leftarrow$ TopKModes($\mathbf{C}^{(t)}, K$) {Identify top-K error modes}
9: `// 2. Mode-Specific Diagnosis Generation`
10: $\mathcal{G} \leftarrow \emptyset$
11: **for** each mode $(i, j) \in \mathcal{M}$ **do**
12: $\mathcal{E}_{i\to j} \leftarrow$ Extract error examples with true label i, predicted j
13: $\mathcal{E}_i^+, \mathcal{E}_j^+ \leftarrow$ Sample high-misconfidence correct examples
14: $g_{i\to j} \leftarrow$ Reflector(Rules$^{(t)}, \mathcal{E}_{i\to j}, \mathcal{E}_i^+, \mathcal{E}_j^+, \mathbf{C}^{(t)}, \mathcal{M}$)
15: $\mathcal{G} \leftarrow \mathcal{G} \cup \{g_{i\to j}\}$
16: **end for**
17: `// 3. Two-Phase Rule Consolidation`
18: $\mathcal{R} \leftarrow \emptyset$
19: **for** each $(i, j) \in \mathcal{M}$ **do**
20: $r_{i\to j} \leftarrow$ Refiner(Rules$^{(t)}, g_{i\to j}, \mathcal{M} \setminus \{(i, j)\}, \mathbf{C}^{(t)}$)
21: $\mathcal{R} \leftarrow \mathcal{R} \cup \{(r_{i\to j}, (i, j))\}$
22: **end for**
23: $r_{\text{consolidated}} \leftarrow$ PriorityConsolidate($\mathcal{R}, \mathbf{C}^{(t)}$)
24: `// 4. Candidate Expansion and Selection`
25: $\mathcal{P}_{\text{new}} \leftarrow \{\mathcal{P} \oplus r : \mathcal{P} \in \mathcal{P}^{(t-1)}, r \in \mathcal{R} \cup \{r_{\text{consolidated}}\}\}$
26: Score each $\mathcal{P} \in \mathcal{P}_{\text{new}}$ via UCB-based evaluation
27: $\mathcal{P}^{(t)} \leftarrow$ DiverseSelect($\mathcal{P}_{\text{new}}, B, \lambda$) {Eq. 5}
28: **end for**
29: **return** $\arg\max_{\mathcal{P} \in \mathcal{P}^{(T)}} \kappa(\mathcal{P}, \mathcal{D}_{\text{val}})$

4.3 Mode-Specific Feedback Generation

To repair the identified errors, CARO avoids the "rule dilution" of baseline methods by generating separate diagnosis for each error mode (lines 10–16). We employ a Reflector LLM to analyze the confusion pattern (i, j) specifically. The gradient generation process is formalized as:

$$g_{i\to j} = \text{Reflector}(\text{Rules}^{(t)}, \mathcal{E}_{i\to j}, \mathcal{E}_i^+, \mathcal{E}_j^+, \text{GlobalContext}(\mathbf{C}), \mathcal{M}) \tag{3}$$

Here, $\mathcal{E}_i^+$ and $\mathcal{E}_j^+$ represent the contrastive correct examples. We have shown a demonstration of the Reflector's prompt in Figure 2.

As exemplified by Figure 3, the resulting gradient $g_{i\to j}$ provides a structured diagnosis, identifying the root cause of the confusion, creating discriminative criteria to distinguish score i from j, and performing a safety check to predict potential negative side effects on other score categories.

4.4 Two-Phase Rule Consolidation

Reflector Prompt for Mode $(0 \to 1)$ Confusion

[GLOBAL CONTEXT]

True\Pred	**0**	**1**	**2**
0	6	**25**	7
1	0	9	10
2	0	0	7

Error Distribution:
- $0 \to 1$: 25 errors (59.5%) ← *CURRENT FOCUS*
- $1 \to 2$: 10 errors (23.8%)
- $0 \to 2$: 7 errors (16.7%)

[LOCAL ERROR EXAMPLES] $\mathcal{E}_{0\to1}$

Example 1: "*They understand it partially because I understand what they are doing but I would show them that setting it up as a proportion makes more sense.*"
True: 0 **Pred:** 1 **Reasoning:** Teacher acknowledges some understanding but lacks specific analysis...

Example 2: "*His explanation doesn't really refer to the equivalent ratios. Although the actual work seems to show he has some understanding.*"
True: 0 **Pred:** 1 **Reasoning:** Vague acknowledgment without depth...

[CONTRASTIVE CORRECT EXAMPLES] $\mathcal{E}_0^+, \mathcal{E}_1^+$

Correctly Classified as 0	**Correctly Classified as 1**
"*Student A has a limited understanding because he based his answer on the dollar amount.*" → Incorrect/generic analysis	"*The student looked at price versus amount to find the unit rate.*" → Procedural description of student work

[TASK] Analyze WHY the $0 \to 1$ confusion occurs. Identify misleading patterns and propose rule fixes.

Figure 2: Example Reflector prompt for analyzing the dominant error mode $(0 \to 1)$. The prompt provides: (1) global context via the full confusion matrix, (2) local error examples with model reasoning traces, and (3) contrastive correct examples to establish decision boundaries.

A critical innovation of CARO is the consolidation strategy, which converts discrete error diagnostics into a unified, coherent rubric (lines 18–23). We execute this in two phases to balance specificity with logical consistency.

Phase 1: Per-Mode Rule Generation. We translate the gradients into specific rule refinements (lines 19–22). For each mode (i, j), a Refiner module generates a rule update $r_{i\to j}$. Crucially, the Refiner receives information about all other targeted error modes $\mathcal{M}\backslash\{(i, j)\}$ as additional context. This *cross-mode awareness* enables the Refiner to anticipate potential interactions. We show an example of the prompt to Refiner in Figure 4: when generating a rule to prevent $0 \to 1$ misclassification, it can avoid phrasing that would inadvertently increase $1 \to 2$ or $0 \to 2$ errors if these modes are also being addressed in the same round.

Phase 2: Priority-Weighted Consolidation. Rather than simply concatenating all new rules, which often leads to bloated or contradictory prompts, we organize rules based on the frequency of the error modes they address (line 23). The consolidated rule set for the next iteration is derived as:

$$\text{Rules}^{(t+1)} = \text{Consolidate}(\{r_{i\to j}\}_{(i,j)\in\mathcal{M}}, \mathbf{C}) \tag{4}$$

As shown in Figure 5, the consolidation assigns explicit precedence levels: the dominant error mode (highest C_{ij}) receives Priority 1 with 2–3 detailed rules; secondary modes receive Priority 2+ with single-sentence guards. When rules from different priority levels suggest different scores for an edge case, we insert explicit *tie-breaker directives*, e.g., "If Priority 1 criteria suggest score X but Priority 2 criteria suggest score Y, assign score X unless [specific exception condition]." This prioritization ensures that the optimization creates a stable "diagnosis-and-repair" pipeline, systematically eliminating the most significant failure patterns before addressing long-tail errors.

4.5 Candidate Selection and Sampling

The final phase bridges the current iteration to the next by performing two distinct operations (lines 24–26): (1) *candidate selection*, which determines which prompt variants effectively resolved errors and should survive to the next round, and (2) *minibatch sampling*, which constructs the optimal training data for the subsequent iteration to prevent overfitting and ensure robust evaluation.

Diversity-Aware Candidate Selection. CARO maintains a beam of B candidate prompts across iterations. Each candidate prompt $\mathcal{P}$ generated in "Two-Phase Rule Consolidation" is tagged with its target mode $m(\mathcal{P}) \in \mathcal{M}$, indicating which confusion cell it was designed to address. To prevent the beam from collapsing to variants of a single mode fix, we employ a greedy selection strategy that balances empirical performance with mode coverage:

$$\text{SelectScore}(\mathcal{P}) = \widetilde{\kappa}(\mathcal{P}) + \lambda \cdot \mathbb{1}[m(\mathcal{P}) \notin \mathcal{S}] \tag{5}$$

where $\widetilde{\kappa}(\mathcal{P})$ is the min-max normalized Cohen's κ score [7], $\mathcal{S}$ represents the set of error modes already covered by previously selected candidates in the current selection round, and λ is a hyperparameter controlling the diversity bonus. The indicator function $\mathbb{1}[\cdot]$ awards a bonus to candidates targeting modes not yet represented in the selected set $\mathcal{S}$, encouraging exploration of diverse rule modifications.

Reflector Output: Diagnosis $g_{0\to1}$

Root Cause:
The classifier misinterprets teachers' acknowledgment of "some understanding" as sufficient for Score 1. Phrases like "valid reasoning" or "understands partially" mislead the classifier despite lacking analytical depth.

Misleading Patterns:
- Positive language ("some understanding", "valid reasoning")
- Missing specific evidence from student work
- Vague acknowledgments without multiplicative analysis

Why These Are 0, Not 1:
Per rubric: Score 0 for responses that provide *generic* or *absent* analysis. Simply stating "valid reasoning" $\neq$ analyzing mathematical thinking.

Proposed Rule Fix:
❶ Responses acknowledging partial understanding **must** include specific examples demonstrating multiplicative relationships.
❷ Vague acknowledgments without detailed analysis $\Rightarrow$ Score 0.

Safety Check:
This fix reinforces depth requirements, which aligns with addressing $1 \to 2$ errors (also require specificity). Will not increase other error modes.

Figure 3: Structured diagnosis output from the Reflector for mode $(0 \to 1)$. The output identifies root causes, misleading patterns, and proposes targeted rule modifications with safety considerations.

Semantic Minibatch Sampling. Instead of random minibatch construction, we use an SBERT [24]-based similarity selector to focus optimization effort on challenging regions of the input space. We retrieve training examples that are semantically similar to the high-misconfidence instances identified in previous rounds:

$$\text{Minibatch}^{(t)} = \bigcup_{x \in \text{TopMisconf}^{(t-1)}} \text{kNN}_k(x, \mathcal{D}_{\text{train}}) \quad (6)$$

where kNN_k retrieves the k nearest neighbors based on SBERT embeddings. This ensures that refined rules are stress-tested against examples where the current rubric is most ambiguous, accelerating convergence on difficult boundary cases.

4.6 Inference with Optimized Prompt

Upon the termination of the optimization procedure, we select the rubric prompt $\mathcal{P}^*$ that maximizes the evaluation metric (Cohen's κ) on the validation set:

$$\mathcal{P}^* = \arg\max_{\mathcal{P} \in \mathcal{P}^{(T)}} \kappa(\mathcal{P}, \mathcal{D}_{\text{val}}) \quad (7)$$

This globally optimized prompt serves as the fixed instruction set for the final inference phase on the held-out test dataset $\mathcal{D}_{\text{test}}$. For a given student response $x \in \mathcal{D}_{\text{test}}$, the predicted score is obtained as:

$$\hat{y} = \arg\max_{y \in \mathcal{Y}} P_\theta(y \mid x, \mathcal{P}^*) \quad (8)$$

where $P_\theta(y \mid x, \mathcal{P}^*)$ denotes the probability assigned by the LLM predictor f_θ to score y given the student response x and the optimized rubric $\mathcal{P}^*$. The model generates a completion

Refiner Prompt for Rule Generation

[INPUT]
- Current rules: $\text{Rules}^{(t)}$
- Diagnosis: $g_{0\to1}$ (from Reflector)
- Error examples: $\mathcal{E}_{0\to1}$
- Other modes: $\{(1,2),(0,2)\}$ ← *Cross-mode awareness*

[CONSTRAINTS]
❶ Fix must target $0 \to 1$ confusion specifically
❷ Must NOT break existing correct classifications
❸ Must be COMPATIBLE with fixes for $(1 \to 2)$, $(0 \to 2)$
❹ Edit budget: `medium` (2–3 new rules)

[OUTPUT FORMAT]
Generate improved rules that:
- Include clear distinguishing criteria
- Use specific patterns from error analysis
- State safety considerations for other modes

Figure 4: Refiner prompt structure showing how cross-mode awareness is incorporated. The Refiner receives information about all active error modes to generate compatible rule fixes.

that includes both a reasoning trace r and a final numerical score, extracted via regular expression parsing:

$$(\hat{y}, r) = \text{Parse}\big(f_\theta(x \oplus \mathcal{P}^*; \tau = 0)\big) \quad (9)$$

By enforcing the reasoning trace through the structure of $\mathcal{P}^*$, the inference process provides not only a quantitative grade but also an interpretable justification that reflects the resolved decision boundaries established during optimization.

5. EXPERIMENTS

5.1 Experimental Setup

Datasets. We evaluate CARO on three educational grading datasets spanning K-12 science education and teacher education:

Interaction Dataset ($\mathcal{D}_I$): This dataset contains 252 high school student responses to a physics assessment item on electrical interactions [15]. Each response is evaluated against 11 binary rubric categories (labeled 0/1), where 0 indicates the requirement is "not met" and 1 indicates it is "met." The categories assess distinct aspects of student understanding, ranging from basic concept recognition to complex reasoning about charge interactions.

Elementary Item Response Dataset ($\mathcal{D}_E$): This dataset comprises elementary student responses to five science assessment tasks graded on an ordinal scale $\{0, 1, 2, 3, 4\}$. The tasks assess foundational science concepts with varying levels of complexity.

Teacher Education Dataset ($\mathcal{D}_T$): This dataset evaluates teachers' pedagogical content knowledge in mathematics education [8]. It contains eight grading tasks organized into three knowledge dimensions:

- **KSMT** (Knowledge of Students' Mathematical Thinking): Tasks T1–T3 assess teachers' ability to interpret

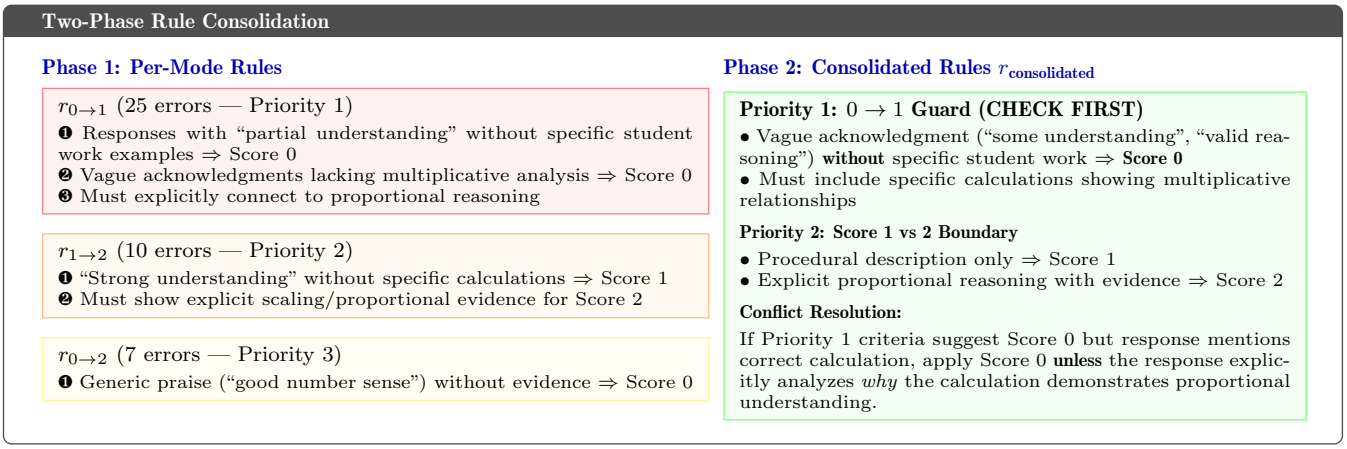

Figure 5: Two-phase rule consolidation. Phase 1 generates per-mode rules with cross-mode awareness. Phase 2 synthesizes them into a priority-weighted consolidated ruleset with explicit conflict resolution directives.

student mathematical reasoning.

- **KMT** (Knowledge of Mathematical Tasks): Tasks T4–T6 evaluate understanding of task design and cognitive demand.
- **KT** (Knowledge of Teaching): Tasks T7–T8 assess pedagogical decision-making.

All tasks in $\mathcal{D}_T$ use ordinal labels $\{0, 1, 2\}$, representing absent, partial, and complete understanding respectively.

We partition each dataset into train/validation/test splits using a 7:1:2 ratio following [6]. Dataset statistics are summarized in Table 1.

Table 1: A summary of statistics of the datasets

Dataset	Domain	#Samples	Scores
$\mathcal{D}_I$	Interaction	252	{0,1}
$\mathcal{D}_T$	Teacher Education	224∼236	{0,1,2}
$\mathcal{D}_E$	Elementary	199∼434	{0,1,2,3,4}

Baselines. We compare CARO against two baselines. First is **Naive Prompting**, which uses direct zero-shot prompting with an expert-written rubric, without any optimization. Secondly, we compare with **GradeOpt** [6], a state-of-the-art automatic prompt optimization framework that iteratively refines rubrics using aggregated error feedback.

Implementation Details. We use `GPT-4o-mini` as both the grading predictor f_θ and the optimization agents (Reflector and Refiner) across all methods for fair comparison. For CARO, we set: top-K error modes $K = 4$, beam size $B = 4$, diversity weight $\lambda = 0.3$, and maximum rounds $T = 6$. The edit budget is set to "medium" (2–3 rule modifications per mode). For GradeOpt, we use the default hyperparameters from [6] and set the maximum rounds to $T = 6$ to align with computational constraints of CARO. To mitigate the inherent stochasticity of LLM generation and ensure the reliability of our findings, we conducted 3 independent runs for all methods (CARO and baselines) across each task. The reported results represent the average performance on the held-out test set across these 3 trials.

Evaluation Metrics. We report classification accuracy (Acc) and Cohen's κ coefficient [7]. While accuracy measures overall correctness, κ accounts for class imbalance and chance agreement, making it the primary metric for grading reliability assessment. A $\kappa > 0.6$ is generally considered substantial agreement [17].

5.2 Main Results

Teacher Education Dataset ($\mathcal{D}_T$). Table 2 presents results on the teacher education dataset. CARO achieves consistent improvements across all eight tasks, with an average accuracy improvement of +11% over GradeOpt and +41% over Naive prompting.

Table 2: Performance Comparison for Teacher Education Dataset $\mathcal{D}_T$

Type	Task	Naive		GradeOpt		CARO	
		Acc	κ	Acc	κ	Acc	κ
KSMT	T1	0.40	0.20	0.61	0.41	0.67	0.47
KSMT	T2	0.58	0.42	0.74	0.61	0.79	0.69
KSMT	T3	0.39	0.09	0.51	0.25	0.55	0.30
KSMT	**Avg**	**0.46**	**0.24**	**0.62**	**0.42**	**0.67**	**0.49**
KMT	T4	0.30	0.05	0.55	0.28	0.76	0.57
KMT	T5	0.59	0.28	0.60	0.31	0.74	0.46
KMT	T6	0.68	0.44	0.76	0.58	0.76	0.59
KMT	**Avg**	**0.52**	**0.26**	**0.64**	**0.39**	**0.75**	**0.54**
KT	T7	0.45	0.29	0.74	0.60	0.77	0.65
KT	T8	0.60	0.34	0.70	0.48	0.72	0.52
KT	**Avg**	**0.52**	**0.32**	**0.72**	**0.54**	**0.75**	**0.59**
Overall	**Avg**	**0.51**	**0.27**	**0.65**	**0.44**	**0.72**	**0.53**

The most substantial gains occur on tasks with severe baseline confusion patterns. For instance, on T4 (KMT), CARO improves κ from 0.28 (GradeOpt) to 0.57, which is a relative improvement of 104%. This task exhibits significant $0 \to 1$ confusion in the baseline, which CARO directly addresses through mode-specific gradient generation. Similarly, T5 shows a κ improvement from 0.31 to 0.46, demonstrating CARO's effectiveness on tasks where GradeOpt's aggregate

feedback fails to resolve specific confusion patterns. Notably, CARO's improvements are most pronounced in the KMT dimension, where grading criteria involve subtle distinctions between "no understanding" and "partial understanding", which is precisely the type of adjacent-class confusion that CARO is designed to resolve.

Interaction Dataset ($\mathcal{D}_I$). Table 3 shows results on the binary classification tasks. Despite the simpler label space, several categories exhibit class imbalance that inflates accuracy while depressing κ. CARO achieves the highest κ on 10 of 11 categories. The improvements are particularly striking on challenging categories:

- **Category 3**: κ improves from 0.61 (GradeOpt) to 0.89, a 46% relative gain.
- **Category 4**: κ improves from 0.36 to 0.62, resolving severe confusion in this low-agreement task.
- **Category 8**: Accuracy jumps from 0.44 to 0.74 (+68%), with κ improving from 0.04 to 0.12.

Categories 6, 8, and 9 exhibit persistently low κ despite high accuracy improvements, indicating extreme class imbalance where the minority class remains difficult to identify. Nevertheless, CARO substantially outperforms baselines in accuracy, suggesting improved discrimination even when κ is constrained by distributional factors.

Table 3: Performance Comparison for Interaction Dataset $\mathcal{D}_I$

Category	Naive		GradeOpt		CARO	
	Acc	κ	Acc	κ	Acc	κ
1	0.94	0.79	0.96	0.84	0.98	0.92
2	0.86	0.71	0.88	0.76	0.93	0.87
3	0.82	0.52	0.85	0.61	0.95	0.89
4	0.52	0.19	0.64	0.36	0.81	0.62
5	0.62	0.18	0.95	0.72	0.96	0.78

Avg	**0.58**	**0.25**	**0.75**	**0.43**	**0.90**	**0.55**

Table 4: Performance Comparison for EIR Dataset $\mathcal{D}_E$

Task	Naive		GradeOpt		CARO	
	Acc	κ	Acc	κ	Acc	κ
T1	0.16	-0.08	0.63	0.35	0.63	0.39
T2	0.49	0.30	0.74	0.64	0.75	0.66
T3	0.57	0.25	0.79	0.67	0.81	0.70
T4	0.48	0.20	0.71	0.57	0.74	0.62
T5	0.50	0.04	0.70	0.46	0.73	0.56
Avg	**0.44**	**0.14**	**0.71**	**0.54**	**0.73**	**0.59**

Elementary Item Response Dataset ($\mathcal{D}_E$). Table 4 presents results on the elementary response dataset. CARO achieves consistent improvements across all five tasks, with an average κ of 0.59 compared to 0.54 for GradeOpt and 0.14 for Naive prompting. The most notable improvement occurs on T5, where κ increases from 0.46 (GradeOpt) to 0.56, which represents a 22% relative improvement. This task involves distinguishing between partial and complete understanding, a boundary that benefits from CARO's contrastive example selection.

Table 5: Summary of average performance across datasets.

Dataset	Naive		GradeOpt		CARO	
	Acc	κ	Acc	κ	Acc	κ
$\mathcal{D}_I$ (avg)	0.58	0.25	0.75	0.43	**0.90**	**0.55**
$\mathcal{D}_T$ (avg)	0.51	0.27	0.65	0.44	**0.72**	**0.53**
$\mathcal{D}_E$ (avg)	0.44	0.14	0.71	0.54	**0.73**	**0.59**
Overall	0.51	0.22	0.70	0.47	**0.78**	**0.56**

Summary of Improvements. Table 5 summarizes the aggregated performance across all datasets. On average, CARO improves accuracy from 0.51 (Naive prompting) to 0.78, representing a 53% increase compared to GradeOpt (37% increase from 0.51 to 0.70). CARO achieves an overall average κ of 0.56, representing a 19% relative improvement over GradeOpt (0.47) and a 155% improvement over Naive prompting (0.22).

5.3 Ablation Studies

We conduct ablation studies to analyze the key design choices and advantages of CARO.

Per-Mode vs. Consolidated Rules. As described in Section 3.4, CARO generates two types of candidate rules during the Two-Phase Rule Consolidation: (1) **per-mode rules** $r_{i \to j}$ that target individual confusion cells, and (2) **consolidated rules** $r_{\text{consolidated}}$ that synthesize all per-mode rules into a unified, priority-weighted ruleset via Eq. 4. Both types are included in the candidate pool (Algorithm 1, line 24), and the diversity-aware selection mechanism (Eq. 5) determines which candidates propagate to subsequent rounds. Table 6 reports which candidate type achieves the best validation κ across all tasks.

We observe that per-mode rules are selected as the final best prompt in over 90% of cases across all datasets. This indicates that targeted fixes for specific confusion cells typically outperform holistic rewrites that attempt to address multiple error patterns simultaneously. The consolidated rules, despite being carefully synthesized with priority weighting and conflict resolution directives, tend to dilute the specificity needed for precise decision boundaries. However, consolidated rules are occasionally preferred (6–8% of cases) in tasks with strongly interacting error modes, where coherent integration prevents the rule conflicts that can arise from independently applying multiple per-mode fixes.

Convergence Analysis. Figure 6 shows the optimization trajectory across rounds for a representative task T4 in $\mathcal{D}_I$

Table 6: **Ablation: Per-mode vs. consolidated rule selection. Values show the percentage of final best prompts using each strategy.**

Dataset	Per-Mode	Consolidated	Best κ
$\mathcal{D}_I$	93.9%	6.1%	Per-Mode
$\mathcal{D}_T$	91.7%	8.3%	Per-Mode
$\mathcal{D}_E$	93.3%	6.7%	Per-Mode
Avg	93.0%	7.0%	-

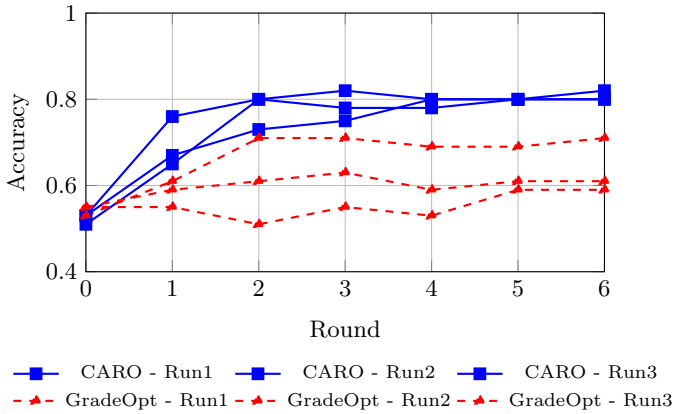

Figure 6: Convergence comparison on T4 ($\mathcal{D}_I$). CARO achieves faster convergence and higher final accuracy.

Table 7: **API cost comparison (average per task). Costs estimated using GPT-4o-mini pricing ($0.15/1M input, $0.60/1M output tokens).**

Method	Rounds	API Calls	Est. Cost
GradeOpt	6	∼40,000	∼$5
CARO	6	∼8,000	∼$2
Reduction	–	80%	60%

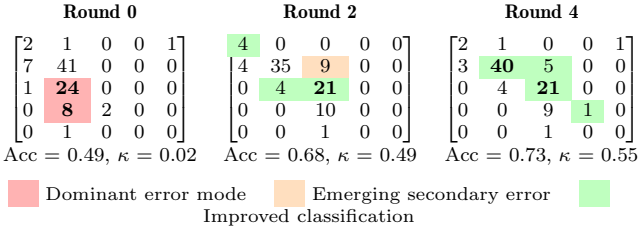

Figure 7: Confusion matrix progression on T5 ($\mathcal{D}_E$). Rows represent true labels; columns represent predictions. CARO's iterative refinement first resolves the dominant $2 \to 1$ collapse (Round 0–2), then addresses the emergent $1 \to 2$ over-correction (Round 2–4), achieving balanced diagonal improvement.

over three independent runs. Several patterns emerge from this comparison.

Rapid initial gains. CARO demonstrates substantially faster early-stage improvement, achieving an average accuracy of 0.69 after just one round (from 0.52 baseline), compared to GradeOpt's 0.58. By Round 2, all CARO runs reach or exceed 0.73 accuracy, while all GradeOpt runs remain below 0.71.

Stability vs. oscillation. CARO exhibits monotonic or near-monotonic improvement with stable convergence around 0.80 accuracy by Round 3–4. In contrast, GradeOpt displays the oscillation characteristic of aggregate feedback methods: Run 2 drops from 0.55 to 0.51 at Round 2, and Run 1 regresses from 0.63 to 0.59 at Round 4. This instability reflects mode interference, where fixing one error pattern inadvertently amplifies another.

Final performance gap. After 6 rounds, CARO achieves a final accuracy of 0.80–0.82 across all runs (avg. 0.81), while GradeOpt plateaus at 0.59–0.71 (avg. 0.64). This gap demonstrates that CARO's mode-specific updates not only converge faster but also reach superior optima by avoiding the destructive interference inherent in consolidated feedback approaches.

API Cost Analysis. Table 7 compares the computational cost of CARO and GradeOpt. Despite using the same number of optimization rounds, CARO requires 80% fewer API calls, translating to approximately 60% cost reduction. This efficiency benefits from CARO's targeted optimization strategy: rather than exhaustively sampling errors across all confusion cells to generate aggregate feedback, CARO focuses gradient generation on only the top-K error modes per round. Additionally, the mode-specific Reflector and Refiner operate on refined subsets of error examples (Eq. 3), whereas GradeOpt's aggregate approach requires broader sampling to capture diverse error patterns within a single feedback signal.

5.4 Qualitative Analysis

Case Study: Iterative Error Resolution on T5 ($\mathcal{D}_E$). We illustrate CARO's "diagnosis-and-repair" pipeline through a detailed case study on T5 ($\mathcal{D}_E$), which assesses elementary students' understanding of how a Peregrine Falcon perceives a rock pigeon through a four-step light perception process (light travels to pigeon → reflects off pigeon → enters falcon's eyes → brain processes images). The task uses a 5-point ordinal scale $\{0, 1, 2, 3, 4\}$ where Score 2 requires mentioning 1–2 steps, while Score 1 is reserved for responses containing no accurate steps. Figure 7 traces the confusion matrix evolution across optimization rounds, revealing how CARO systematically resolves cascading error patterns.

Round 0: Identifying the Dominant Mode. The initial classifier exhibits severe collapse toward Score 1, with the $2 \to 1$ cell containing 24 errors (53% of all misclassifications, highlighted in red). Analysis reveals that responses mentioning partial steps, such as *"the light source is the sun and the light travels to the eye and that's how the falcon can see the pigeon"*, were incorrectly penalized for omitting steps rather than credited for partial understanding. A secondary $3 \to 1$ pattern (8 errors) compounds this collapse, resulting

in zero correct predictions for Scores 2–4 and a near-chance $\kappa = 0.02$.

Round 2: Resolving the Primary Collapse. CARO's Reflector diagnoses the root cause: the original rubric lacks explicit guidance for recognizing partial scientific understanding. The generated rule states: *"If a response includes at least one correct element related to the four steps (e.g., light traveling, reflecting, or entering the eyes), classify as Score 2, provided it does not contain entirely irrelevant information."* As shown in the Round 2 matrix, this intervention reduces $2 \rightarrow 1$ errors from 24 to 4 (-83%, green), while correct Score-2 predictions increase from 0 to 21. Class 0 achieves perfect classification (orange). However, the fix reveals an emergent secondary pattern: $1 \rightarrow 2$ confusion (9 errors, orange) as the model now over-awards partial credit to responses lacking any valid steps.

Round 4: Addressing the Secondary Mode. CARO shifts focus to the $1 \rightarrow 2$ over-correction, introducing a discriminative rule: *"Responses must include at least one identifiable step describing light's journey; vague statements about 'seeing' without mechanistic detail remain Score 1."* The Round 4 matrix shows this refinement reduces $1 \rightarrow 2$ errors from 9 to 5 while improving Score-1 correct predictions to 40 (up from 35). Crucially, the $2 \rightarrow 1$ gains are preserved (4 errors), and Score 3 achieves its first correct prediction. The final $\kappa = 0.55$ reflects balanced diagonal improvement across all classes.

This progression exemplifies CARO's core mechanism. Instead of treating error reduction as a single, monolithic task, the framework isolates specific confusion patterns within the matrix. This decomposition turns a complex optimization challenge into a sequential and interpretable repair process. Crucially, this step-by-step approach ensures that corrections for one error type build upon previous improvements without causing regression in other classes.

6. DISCUSSION

The experimental results demonstrate that the Confusion-Aware Rubric Optimization (CARO) framework significantly advances the state of automated grading by addressing the structural inefficiencies of prior prompt optimization methods. While existing frameworks such as GradeOpt rely on aggregating heterogeneous error signals, our findings confirm that such aggregation leads to rule dilution, where the optimizer struggles to satisfy conflicting constraints simultaneously. By decomposing the optimization context into distinct error modes via the confusion matrix, CARO transforms the complex prompt refinement into a series of targeted repairs.

A primary implication of this study is the relationship between optimization specificity and efficiency. Our analysis reveals that CARO achieves superior performance with approximately 60% lower computational costs compared to baseline methods. This efficiency stems from the mode-specific gradient generation, which prevents the optimization process from cycling through redundant rule changes. Instead of requiring extensive exploration to find a marginally better prompt, the structured diagnosis allows the model to identify and resolve dominant failure patterns, such as the confusion between partial and complete understanding, with the first few iterations. This suggests that for ordinal grading tasks, structural error analysis (with confusion matrix) is a more resource-efficient method for improvement than simply increasing the volume of feedback or the size of the optimizer model.

Furthermore, the pedagogical utility of automated assessment relies heavily on interpretability and trust. This distinguishes our approach from traditional automated grading methods, such as latent semantic analysis or BERT-based fine-tuning, which process inputs through high-dimensional vectors and lack visibility into the decision-making process. Unlike these earlier supervised pipelines that function as black-box systems, CARO optimizes the natural language rubric itself. The resulting prompts contain explicit reasoning traces and priority-weighted decision rules. This transparency allows educators to validate the grading criteria before deployment, ensuring that automated system aligns with instructional goals.

Despite these strengths, there are limitations to consider. The current framework relies on the capability of the backbone LLM to self-reflect and generate diagnostic feedback. While our experiments utilized `GPT-4o-mini` effectively, the performance of CARO on smaller, open-source models remain an area for future investigation.

7. CONCLUSION

This study introduced Confusion-Aware Rubric Optimization (CARO), a novel framework designed to bridge the alignment gap between expert grading criteria and LLM logic. By identifying that grading errors are not random noise but structured clusters, we developed a method that replaces aggregate feedback with mode-specific diagnosis and repair. Through the systematic decomposition of confusion matrices, CARO isolates specific misclassification patterns and generates targeted rule patches that resolve ambiguities without degrading global performance.

Our empirical evaluation across three distinct educational datasets confirms that CARO significantly outperforms state-of-the-art prompt optimization methods in both accuracy and inter-rater reliability. Critically, the framework achieves these gains while reducing computational overhead, offering a scalable solution for high-quality formative assessment. By providing a transparent, efficient, and precise method for rubric refinement, CARO represents a substantial step reliable and scalable automated feedback in complex learning environments.

ABSTRACT

Data-Driven Classroom Interview (DDCI) uses real-time student data to identify important learning events and support the collection of rich in-situ interviews at critical moments of the learning process. Because DDCI occurs during the students' use of the learning system, they may introduce reactivity, whereby participation in the research may alter the experience of the learners. This study investigates short-term behavioral reactivity associated with DDCI and examines a potential mechanism—the attention cue effect—within What-If Hypothetical Implementations in Minecraft (WHIMC), a game-based learning environment. We used log data to compare the learning behaviors of interviewed and non-interviewed students on a set of key WHIMC behaviors, including movement, scientific observation, and measurement tool use. Results show that DDCI is associated with significant behavioral reactivity for behaviors that are more intentional and goal directed (student in-game observations and tool usage) but not for a third behavior (movement), which may function as less direct, peripheral byproduct of task engagement. Moreover, reactivity was not explained by explicit discussions of these behaviors during DDCI, which may indicate that reactivity is arising through other mechanisms. By empirically documenting short-term behavioral reactivity in DDCI and systematically examining its potential mechanisms, this study contributes to the methodological refinement of DDCI and highlights important considerations for the design and interpretation of data-driven research in open-ended learning environments.

1. INTRODUCTION

Data-Driven Classroom Interview (DDCI) is a research method designed to deepen our understanding of learning phenomena by complementing traditional in-situ interviews using detectors based on learner modeling methods [1, 20]. While in-situ interviews have been used to capture learners' experiences and meanings within authentic learning contexts, they face two persistent methodological challenges [1]. First, researchers must determine how to identify rare yet pedagogically important events that are difficult to observe directly, often described as a "needle-in-a-haystack" " problem [1]. Second, in-situ interviews raise a sampling issue [22, 25], namely, deciding whom to interview and when, without relying solely on convenience or researcher intuition. By operationalizing theoretically and empirically meaningful learning behaviors through log data to inform interview opportunities, DDCI enables researchers to capture critical yet otherwise elusive learning events and to interview participants based on principled criteria [20].

DDCI belongs to a range of in situ methods--including more traditional interviewing techniques, think-aloud protocols [8], and ecological momentary assessment (EMA; [19])--that can improve validity by allowing the researcher access to the students thoughts about the learning experience as it unfolds. However, just like other in-situ research methods, DDCI alters the learning environment for at least the duration of that research activity, and possibly beyond. These measurement effects have a range of labels in the literature including the observer effect [30] or reactivity [4, 34]. Such effects may stem from increased awareness of being observed (the Hawthorne effect; [18]), motivational responses to perceived evaluation or comparison (the John Henry effect; [27]), or attempts to align with perceived researcher expectations (the observer-expectancy effect; [26]). Whereas earlier methodological traditions often sought to eliminate or control reactivity, recent scholarship increasingly emphasizes explicitly investigating and articulating reactivity as part of the research process [17, 34].

Several considerations are particularly important for investigating reactivity in the context of DDCI. First, reactivity research should examine behaviors that are directly logged by the system and that simultaneously relate to learning processes. Reactivity may manifest across multiple domains, including emotion, behavior, and metacognition. Prior work in educational contexts has explored some of these dimensions. For example, Liu et al. [16] found that observation influenced students' display of emotional states by increasing engaged concentration while reducing frustration and off-task behavior. Similarly, Bosch et al.'s [3] analysis of metacognitive content in DDCI found that certain forms of verbalized metacognition were associated with learning outcomes, particularly for students who engaged in metacognitive verbalization during

interviews. However, these studies did not directly examine behavioral changes in the log data that serve as the triggering events for DDCI and may also represent important learning behaviors. This omission is consequential, as changes in logged behavior may alter detector activation, subsequent interview selection, and, ultimately, interpretations of learning.

In addition, systematic approaches to studying reactivity should be considered. Reactivity can be more rigorously examined by (1) comparing participants' behaviors before and after the measurement of interest, thereby leveraging temporal changes associated with repeated measurement [10], and (2) employing between-participant comparisons between students who are measured and those who are not, in order to distinguish reactivity from other confounding factors. In the DDCI context, prior logged behaviors may determine which students are interviewed, and reactivity may be intertwined with both interview-related influences and observer effects. Therefore, research on DDCI reactivity should consider both students' behaviors before interviews and the behaviors of non-interviewed peers to control the observer effects.

Finally, understanding the mechanisms underlying reactivity is crucial for explaining why reactivity occurs and how it can be mitigated in DDCI settings. Several mechanisms may plausibly explain DDCI-related reactivity, including observer effects, verbalization effects, and metacognitive activation. The presence of researchers in the classroom may elicit observer effects, as evidenced by prior findings [16, 30]. Additionally, DDCI interviews require students to engage in high-level verbalization about their thoughts and actions, which is likely to induce stronger reactivity than lower-level verbalization methods such as think-aloud protocols [6, 8]. Such verbalization may function as an attentional cue [4] that stimulates cognitive and metacognitive processes, which can vary depending on both individual characteristics (e.g., interest) and task features (e.g., writing versus reading). Given these multiple plausible mechanisms, researchers should design studies and analyses that aim to identify which mechanisms most plausibly account for observed reactivity effects.

The present study examines whether and how students' behaviors are influenced by DDCI in WHIMC (What-if Hypothetical Implementations in Mine-craft), a Minecraft-based learning environment [9, 14]. Specifically, we investigate reactivity in behaviors that are directly logged by the system by comparing the behaviors of interviewed students to the behavior of peers who were not interviewed during the same activity. When interview-related reactivity is identified, we further examine whether such effects are associated with direct attentional cues, through which explicit references to specific behaviors (e.g., "observation") during the interview may promote subsequent enactment of those behaviors. Based on the observed patterns of reactivity, we discuss potential distortions in DDCI-based analyses. By clarifying the nature and implications of behavioral reactivity in DDCI, this study advances the methodological development and supports the careful implementation of data-driven interviews.

2. RELATED WORK

2.1 Data-Driven Classroom Interview

Data-Driven Classroom Interview (DDCI; [1, 20]) is an emerging research method designed to deepen understanding of learning phenomena by augmenting traditional in-situ interviews with detector technologies. By operationalizing focal learning behaviors through log data, detectors can automatically identify moments when targeted behaviors occur and trigger interviews accordingly. This approach allows researchers to capture critical but otherwise elusive learning events and to interview participants based on theoretically and empirically meaningful criteria. The feasibility of such detectors has been substantially enhanced by advances in learning analytics (LA) and educational data mining (EDM), which have demonstrated that a wide range of learning phenomena can be defined, modeled, and monitored using rich streams of behavioral data, such as interaction logs [29].

The DDCI process typically proceeds as follows [20]. Based on the research questions, researchers first develop behavioral models that define interview triggers—specific patterns of activity that research hopes to investigate. Researchers can assign priorities to different triggers to detect rare or theoretically important behaviors while also distributing interview opportunities across participants. When the DDCI system detects a predefined behavior, it alerts researchers, who can then decide whether and when to conduct an interview. These interviews are typically brief (often under five minutes) to minimize disruption to learners' ongoing activity while capturing highly contextualized and ecologically valid accounts of in-situ experiences. In summary, the core stages of DDCI include trigger development, priority setting, and interviewer engagement following trigger detection.

Because DDCI relies on data-driven technologies, their systematic implementation requires technical infrastructure [20]; triggers must be developed and integrated with the learning environment's logging system to facilitate real-time detection and notification as well as the recording and storage of interview data. To date, this has been conducted with Quick Red Fox (QRF), an open-source server–client Android application that streamlines in-situ data collection by directing interviewers to learners immediately after the occurrence of research-relevant behaviors defined a priori by the research team [20].

By integrating data-driven detection with in-situ interviewing, DDCI offers methodological benefits for both qualitative and quantitative research. While in-situ interviews have been used to capture learners' experiences and meanings within authentic learning contexts [13], they face two persistent methodological challenges [1]. First, researchers must identify rare yet pedagogically significant events that are difficult to observe directly—a challenge often characterized as a "needle-in-a-haystack" problem. Second, in-situ interviews raise a sampling issue [22, 25]: deciding whom to interview and when, without relying primarily on convenience or researcher intuition. DDCI addresses these challenges by leveraging detectors derived from log data.

For quantitative research, behavioral data alone provide limited access to the contextual meanings and latent variables underlying observable actions, which raises concerns related to construct validity and inferential plausibility [32]. Qualitative data such as DDCI can complement purely quantitative approaches by addressing challenges in interpreting behavioral data, particularly when inferring learners' intentions or reasoning from logs alone [1, 11]. DDCI provides learners with opportunities to reflect on and explain their behaviors, generating insights that can inform feature interpretation, model refinement, and theory development.

However, the advantages of in-situ interviews are accompanied by an important methodological concern. Because interviews occur during ongoing learning activities in DDCI, participants may unintentionally alter their behavior in response to being interviewed or to their awareness of research participation. Understanding and accounting for such changes is therefore essential when interpreting data collected through DDCI.

2.2 Reactivity

Reactivity refers to any changes that arise from being measured or participating in research itself, with potential effects on participants' motivation, expectations, affect, and goals [4]. Empirical work has documented reactivity across a range of research methods, including ecological momentary assessment (EMA; [19]), think-aloud protocols [6, 8, 28], and interview-based approaches [3, 23, 24]. In a broad sense, all forms of research participation entail some degree of influence on participants. In any interview-based method, such as DDCI, allocating time for an interview and responding to researchers' questions are intended and necessary influence as a part of data collection process. Therefore, it is important to delimit the scope of reactivity under consideration. Accordingly, the form of reactivity most relevant to the present study is what Zahle [34] terms 'regularly unintended reactivity'—that is, routinely occurring effects of research participation that extend beyond the method's intended influence.

Traditional methodological perspectives, particularly within experimental psychology, have emphasized minimizing or eliminating reactivity [15]. From this standpoint, reactivity is treated primarily as a threat to validity. For instance, introspection-based methods, which require participants to report on their internal cognitive processes through surveys or interviews, have been especially criticized on these grounds. In response, proponents of think-aloud protocols developed theoretical frameworks distinguishing levels of verbalization, arguing that low-level verbalizations—such as articulating information already in working memory—introduce minimal reactivity and can therefore serve as valid data sources [6].

In contrast, other research traditions—particularly qualitative inquiry—have taken a more generative view of participant influence. Rather than framing interview effects as reactivity to be controlled, qualitative researchers often conceptualize them as reflexivity [23]. From this perspective, interviews are understood as opportunities for participants to reflect on, reinterpret, and reorganize their experiences in interaction with the researcher. Prior work has examined both during-interview and post-interview reflexivity, highlighting how participation in research can shape participants' self-understanding over time [23]. This orientation reflects an epistemological stance in which interviews are not treated as neutral pipelines for extracting pre-existing meanings, but as sites of meaning and knowledge construction through interviewer–interviewee interaction [13]. Within this framework, participant influence is not a methodological flaw to be eliminated but a natural and often productive feature of the research process.

More recent methodological work seeks to bridge these perspectives by advocating for a reactivity-transparent approach, in which reactivity is explicitly examined, documented, and analytically incorporated rather than treated solely as bias [17, 34]. Zahle [34] argues that researchers should supplement data with explicit assumptions about reactivity, enabling principled reasoning about how collected data may have been shaped by the research process. Depending on the assumptions adopted, researchers may (a) claim reactivity has been adequately controlled, (b) acknowledge partial reactivity effects, or (c) actively investigate the sources and forms of reactivity to infer how participants might have behaved in the absence of measurement.

Strategies have been proposed for studying reactivity itself rather than treating it exclusively as a source of contamination. Gieles et al. [10], for example, distinguish between direct and indirect approaches to assessing measurement reactivity. Direct approaches examine reactivity by explicitly asking participants about perceived changes resulting from research participation, typically through interviews or self-report questionnaires. These methods provide insight into participants' own interpretations of how measurement influenced their thinking, awareness, or behavior, but they are limited by retrospection, social desirability, and participants' ability to articulate subtle or implicit changes.

Indirect approaches [10], by contrast, examine reactivity by detecting systematic changes in responses over repeated measurement, rather than relying on participants' self-reports about influence. Such approaches are especially relevant in EMA contexts, where repeated self-monitoring may promote reflection or learning. For instance, researchers can compare whether survey-based self-perceptions align more strongly with EMA-recorded experiences after, rather than before, an EMA period to assess how EMA may enhance self-understanding (i.e., reactivity in this context). Patterns of increasing alignment or shifts across measurement phases may indicate that participation in measurement itself altered participants' awareness or behavior. These frameworks provide a foundation for examining reactivity in DDCI, where repeated interviews are conducted in real time.

2.3 Reactivity of Data-Driven Classroom Interview

Because DDCI, like other in-situ methodologies, may introduce multiple sources of reactivity, examining its reactivity is essential to understand and articulate how it affects students' learning experiences. First, DDCI requires researchers to be physically present in the classroom, which may produce observer effects [16, 30]. The visible presence of researchers can heighten students' awareness of being observed and lead them to modify their behavior relative to their typical classroom practices. For example, Liu et al. [16] compared students' emotional states in classroom settings with and without observers and found that researcher observation alone could differentially affect detected emotions—specifically increasing engaged concentration while reducing frustration or off-task behaviors. Such effects may be partly attributable to implicit power asymmetries between interviewers and students. In classroom contexts, interviewers are often perceived as authority figures or evaluators, which may inhibit students from sharing authentic accounts of their experiences [1, 31]. To alleviate the issue, DDCI prioritizes eliciting learners' accounts of their ongoing activities and experiences from their own perspectives [1, 20].

Reactivity in DDCI may also vary depending on the level of verbalization elicited during interviews and the interview strategies used to prompt it. Ericsson and Simon [5, 7] distinguished three levels of verbalization. Level 1 verbalization involves the direct vocalization of inner speech as it occurs, whereas Level 2 verbalization requires verbal encoding and organization of thoughts already present in working memory. Although both levels may slow or extend cognitive processing due to overt verbalization, they are generally assumed not to alter the underlying sequence of thought [6, 8]. In contrast, Level 3 verbalization—often referred to as introspection—requires participants to explain or justify their thinking (e.g., "Why are you solving the problem this way?"). This level introduces additional cognitive demands that can interrupt ongoing cognitive processes and resume them in a qualitatively different state. From this perspective, reactivity in DDCI is not uniform but might depend critically on interview design and the extent to which interview prompts elicit higher levels of reflective or explanatory verbalization.

Empirical evidence supports this distinction. In DDCI contexts where interviewers frequently prompted students to articulate their

problem-solving strategies, Bosch et al. [3] found that interviews were associated with increased learning outcomes, particularly for students who engaged in metacognitive verbalization. These findings suggest that reactivity in DDCI may arise not only from the act of interviewing itself but also from the specific content and cognitive demands of interview or its prompts. Consequently, both interview presence and interview design must be considered when examining DDCI reactivity.

The impact of DDCI can be further understood through metacognitive mechanisms activated by interview content. Double and Birney [4] proposed a theoretical framework that conceptualizes reactivity as arising from changes in the cognitive–metacognitive system induced by measurement. Drawing primarily on research on metacognitive measures such as think-aloud protocols, confidence judgments, and judgments of learning, their framework suggests that measurement directs learners' attention toward particular diagnostic cues—either about their ongoing experience (e.g., perceived difficulty, uncertainty, effort) or about their self-beliefs (e.g., perceived competence or memory ability). Attending these cues influences metacognitive monitoring, which in turn shapes metacognitive control decisions and ultimately affects cognitive performance [4, 12]. These cues function as inputs for diagnosing one's performance or motivation relative to task goals, thereby influencing decisions about strategy selection, effort allocation, and persistence.

Importantly, as Double & Birney [4] showed, the strength and direction of such reactivity depend on multiple interacting factors, including task characteristics (e.g., complexity, novelty, openness) and person characteristics (e.g., prior knowledge, metacognitive skill, motivation). These factors shape how measurement-induced cues are interpreted and acted upon. Accordingly, within this metacognitive framework, reactivity is not viewed as random noise, but as a systematic and theoretically explainable consequence of how measurement interacts with learners' monitoring and control processes. This perspective provides a principled basis for examining reactivity in DDCI and for interpreting its effects on learners' behavior and learning trajectories.

3. METHODS

3.1 WHIMC

WHIMC (What-If Hypothetical Implementation in Minecraft) is a suite of Minecraft-based simulations designed to support astronomy-focused inquiry in order to foster student interest [9, 14]. The WHIMC environment includes thirteen space simulation worlds: two orientation worlds (Rocket Launch and Space Station Hub), six "what-if" Earth scenarios (No Moon, Colder Sun, Tilted Earth, Two Moons, and Earth as Moon), five exoplanet worlds (Trappist, Kepler, Gliese, Cancri, and Brown Dwarf), and a Mars world centered on habitat construction.

Within WHIMC, students explore hypothetical questions by comparing normal Earth to simulated alternative conditions, such as an Earth without the Moon or with a colder Sun. As they navigate these worlds, learners freely explore the environment, identify distinctive features at points of interest (e.g., shorter vegetation or the presence of wind turbines), and use embedded scientific tools (e.g., wind-speed sensors) to make observations and collect data. These interactions encourage students to pose questions or generate hypotheses about observed phenomena (e.g., why plants are shorter in the absence of the Moon or whether stronger winds might be responsible). Figure 1 presents example screen captures of gameplay in WHIMC.

Figure 1. Example of gameplay in WHIMC. Students examine a wind turbine in the Earth without Moon scenario and learn that it serves as a primary source of power generation. They can then measure wind speed and record an observation by asking questions or making inferences (e.g., "Why is the wind so fast?").

To investigate their questions, students seek evidence through multiple forms of in-game scaffolding, including examining environmental features at points of interest, using scientific tools to gather measurements, and interacting with non-playable characters (NPCs) whose quests and floating hints guide inquiry. As students connect observations to data and explanations, their inquiry can progress toward deeper causal understanding of the underlying "what-if" scenario—for example, linking increased wind speeds to faster Earth rotation and ultimately to the Moon's gravitational influence. At the same time, the open-ended design of WHIMC means that inquiry is not strictly linear: students retain substantial autonomy and may pursue multiple exploratory paths as they navigate the simulated worlds.

3.2 Data-Driven Classroom Interviewing

3.2.1 Participants

This study examined data collected from five-day science camps for middle school students that employed WHIMC. On the first day of the camp, participants completed surveys assessing individual interest, prior knowledge, and prior game experience. During the first three days, students explored a series of "what-if" simulation worlds and investigated the distinctive characteristics of each environment. At the conclusion of Day 3, post-surveys measuring individual interest, situational interest, and knowledge were administered. During the final two days of the camp, students engaged in a Mars-based habitat construction activity. Throughout the whole gameplay, Quick Red Fox (QRF), an Android application for conducting DDCI [20], was used to detect predefined behavioral patterns in students' in-game actions (e.g., repeated use of the same scientific tool) and to identify candidates for in-situ interviews.

The dataset analyzed in this study combined data from four camps conducted in different regions of the United States, including the Midwest and Mountain West, during 2024 and 2025. The sample consisted of 98 participants, of whom 44 identified as male, 44 as female, 2 as non-binary, and 8 did not disclose their gender. Regarding racial and ethnic identity, participants included 1 Native American, 45 Black, 31 White, 11 individuals identifying with other ethnicities, and 10 participants who chose not to report their ethnicity. Research and data collection protocol was conducted under approval from the Institutional Review Board of University of

Pennsylvania and secondary analysis of the anonymized data was approved by the Institutional Review Board of University of Illinois at Urbana-Champaign. Participation was voluntary, and all students provided written assent along with parental consent.

3.2.2 Log data from WHIMC

This study used both log data and interview data to investigate interview reactivity. Log data were recorded from the Minecraft server and included students' positional information sampled every two to three seconds (x, y, and z coordinates), records of tool use, and records of observational actions, each with corresponding timestamps.

3.2.3 DDCI from Quick Red Fox (QRF)

DDCI was conducted using Quick Red Fox (QRF), an open-source Android server–client application designed to notify interviewers when participants engage in behaviors of interest specified in advance by the research team [20]. QRF integrates modeling technologies and processes real-time data to identify key moments in learners' experiences, referred to as interview triggers. Researchers can assign priorities to different triggers to detect rare or theoretically important behaviors while also distributing interview opportunities across students. When QRF detects a predefined behavioral pattern, the application notifies researchers, enabling them to decide whether and when to conduct an interview.

Trigger events and interview records are transmitted to a centralized dashboard, collecting logs of interview activity and allowing the research team to monitor interview activity in real time. The dashboard provides information such as trigger identifiers, timestamps, student and interviewer IDs, interviewer decisions to conduct interviews, and whether a second student contributed to an interview (e.g., when a neighboring student chimed in during an interview). Interviews are typically brief (generally under five minutes) to minimize disruption to students' ongoing activities while capturing highly contextualized and ecologically valid accounts of their in-situ experiences. A total of four interviewers participate across the four camps (at least two per camp).

All interviews followed established DDCI interview principles and strategies [20], which emphasize maintaining respectful, non-evaluative relationships with students and eliciting the learners' perspectives on their ongoing activities and experiences. Ocumpaugh et al. [20] describe this as the Big Sister Approach (BSA)--which they explicitly contrast with the Orwellian concept of Big Brother. Interviewers make it clear to the students before DDCI begins that interviewers are not there to enforce student behavior, and their interview approach is designed to reflect that as well. To that end, the BSA permits encouragement, but does not permit instruction or policing of off-task behaviors. An interviewer might offer a worried student gentle confirmation about whether the strategy the student wants to test might work, but students who need instruction should be referred to a teacher or peer during a DDCI.

For several reasons, DDCI blends a mix of questions about the learner and about the learning context. In part, questions about the learner allow the interviewer to build trust, however they are also part of an asset-based approach [21] where the interviewer is searching for knowledge that could be relevant to the learning context, even if the student has not yet made those connections. Although interviewers have access to the DDCI trigger information, they do not immediately ask the student about those constructs. The reason for this is two fold, since (1) it could make students feel surveilled, which could heighten self-presentation effects and (2) it limits the degree to which an interview can determine whether that construct and its associated experiences were salient to the students' game-play experience.

DDCI tends to start with questions like "how are you doing?" and "what strategies are you trying?" as they are open-ended enough to allow students to steer the topics in the initial part of each interview. As the interview progresses, questions may get more probing, and if the constructs associated with the trigger do not emerge, the interviewer may try to introduce them (e.g., asking if the student has deliberately visited any locations when determining how they came across a point of interest in the game). Throughout this process, however, the overarching goal is to encourage students to discuss their current states of metacognition, motivation, and engagement. If the constructs associated with the trigger (e.g., a particular part of the WHIMC game) are clearly not part of that metacognitive process, that is typically useful data for a DDCI study like this one, where the underlying goal is to understand student interest development. Therefore, in this study, interviewers did not always actively try to re-engage on topics directly associated with the trigger.

3.2.4 Pre-Interest Survey

The goal of QRF interviews in this research is to understand students' interest development through WHIMC. To account for individual differences, initial levels of individual interest were included in the analysis. Individual interest was measured using a survey adapted from Boeder et al. [2], which assesses context-independent interest in science across five subscales: Information Seeking, Motivation to Reengage, Persistence, Self-Regulation, and Value. Example items include "I want to know more about science" and "I seek out opportunities to engage in science."

Each subscale comprised four to five items rated on a 7-point Likert scale, ranging from Do Not Agree At All to Very Strongly Agree. The survey was administered on the first day of the camp, prior to students' engagement with the WHIMC activities.

3.3 Analysis

Among the log and interview data, only data from five What-If worlds (Lunar Crater, No Moon, Colder Sun, Tilted Earth, Two Moons) were included. Other activities (e.g., the Mars habitat activity and exoplanet exploration) were excluded due to differences in task designs.

The primary goal of the analysis was to examine whether interviews were associated with changes in students' behaviors during and after the interview. To do so, we compared interviewed and non-interviewed students while controlling for pre-interview behavior. This approach helps disentangle interview effects from other influences such as observer effects or general time-related trends (e.g., declining activity as gameplay progresses) by considering both interview and non-interview cases. To enable direct comparison within a common temporal framework, we constructed a dummy interview time frame which aligned behavioral phases across interviewed and non-interviewed students. For each non-interviewed student in a given world, we determined their dummy interview start and end time by randomly selecting one of the interviewed students in the same world and camp and assigned that student's interview start and end times to the non-interviewed student. In brief, we have a time framework composed of two parts : pre-interview (from world play start to interview start) and during/post-interview (from interview start to world play end).

This analysis focused on three core behaviors in WHIMC: tool use, observation, and movement. These behaviors represent central

learning processes in the environment. Students move through the virtual world to locate relevant information, use scientific tools to explore phenomena, and make observations to document and reflect on their findings.

The number of tool use and observation behaviors were extracted directly from server logs without additional feature transformation. In addition to the count of observation and tool uses, we computed binary variables indicating whether the behavior occurred at least once within a given time window. This decision was motivated by the highly right-skewed count distributions for these behaviors, in which most observations were zero or near zero and a small number exhibited very high counts. Under such conditions, modeling only raw counts can be unstable and disproportionately influenced by rare extreme values. Accordingly, the analysis focused on not just frequency but also behavioral occurrence.

Movement-related features were engineered from positional log data from both phase (pre-interview and during/post-interview) and included mean distance traveled, mean speed, speed standard deviation, mean absolute acceleration, acceleration standard deviation, mean direction-change speed, direction-change speed standard deviation, and the mean of direction changes within three angular ranges (45–90°, 90–150°, and 150–180°).

Player position logs were first grouped per each user, camp, and world. All movement features were derived from two-dimensional spatial coordinates (x, z). To focus spatial navigation, only x (east-west) and z (north-south) coordinate was used while y axis (vertical) was excluded [33]. For each consecutive pair of position samples, stepwise displacement was computed as the Euclidean distance:

$\text{distance}_t = \sqrt{(\Delta x_t)^2 + (\Delta z_t)^2}$ where $\Delta x_t = x_t - x_{t-1}$ and $\Delta z_t = z_t - z_{t-1}$.

Instantaneous speed was then calculated as:

$$\text{speed}_t = \frac{\text{distance}_t}{\Delta t_t}$$

Acceleration was derived as the temporal derivative of speed:

$$\text{accel}_t = \frac{\Delta \text{speed}_t}{\Delta t}$$

Movement direction was computed at each step using the arctangent of the displacement vector:

$\text{heading}_t = atan2(\Delta z_t, \Delta x_t)$, yielding angles in radians within $(-\pi, \pi]$.

Changes in heading between consecutive steps were calculated and wrapped to the principal angle range to account for circularity. The absolute turning angle (in degrees) was then defined as:

$$\text{turn_deg}_t = |\text{heading}_t - \text{heading}_{t-1}| \times \frac{180}{\pi}$$

Angular turn velocity was computed as the rate of heading change per unit time:

$$\text{ang_vel}_t = \frac{\Delta \text{heading}_t}{\Delta t_t}$$

To characterize directional changes, turning events were categorized into three angular bins based on absolute turning angle: 45°–90°, 90°–150°, and 150°–180°

The data had a nested and longitudinal structure: each student participated in one of four camps, explored multiple worlds within the camp, and could be interviewed multiple times. To account for this dependency structure, we used generalized linear mixed-effects models (GLMMs) rather than standard regression. Models were fitted in R (version 4.5.2) using the glmmTMB package (version 1.1.13).

Depending on the distributional characteristics of features, we used different GLMM families. First, time-dependent features were fit with negative binomial GLMMs using during-post interview time as offset: the number of observations, and the number of tool use. Second, binary features are fit with binomial GLMMs: binary observation and binary tool use. Lastly, continuous features, which already accounted for time as part of the feature calculations, are modeled with normal distribution: mean distance, all speed features (mean speed and speed standard deviation), all acceleration features (mean absolute acceleration and acceleration standard deviation), and all angular features (mean absolute angular velocity, standard deviation of angular velocity, and mean of direction changes within three angular ranges (45–90°, 90–150°, and 150–180°)). After fitting the models, statistical significance was determined using the Benjamini–Hochberg false discovery rate correction to control for multiple comparisons and reduce Type I error.

A total of three analyses were conducted. First, because interviews were triggered by data-based behavioral criteria, we examined whether students who were interviewed differed significantly from those who were not in their behaviors prior to the interview. Also, as the goal of the interviews were to gain insights into the students' STEM interest, their pre-interest might influence whether they are interviewed. We tested whether interview status significantly predicted students' pre-interview behaviors and pre-interview interest. In these models, camp and world were included as random effects.

Second, we compared the during-and-post features of interviewed and non-interviewed students while controlling for pre-behavior, interview, their interaction, and pre interest. Because we hypothesized that pre-interview behavior might moderate the effect of the interview, all models were initially fitted with an interaction term between pre-interview behavior and interview status. When neither the interaction nor the main effect of interview status was significant, an additional reduced model excluding the interaction term was fitted to examine potential main effects. Across all models, camp and world were included as random effects. When model convergence issues occurred, the random effect of camp was removed and the model was refitted.

Table 1. Extracted Interview Keywords.

Behaviors	Keywords
Observation	observation
Tool use	tool, measure, airflow, radiation, altitude, atmosphere, radius, tectonic, temperature, gravity, tide, humidity, tilt, magnetic, rotation, oxygen, year, pressure, composition, scale

Lastly, when interview effects were detected, we further tested whether these effects were driven by an attention-cue mechanism. Specifically, we compared students whose interviews explicitly mentioned a target behavior (e.g., observation) with those whose interviews did not mention that behavior. We determined whether an interview contained an attention cue by matching keywords associated to the behavior to the interview transcripts (Table 1). We used only 'observation' for observation as other possible keywords (e.g. observe) can extract many unrelated interviews while, for tool

Table 2. Mean and Standard Deviation of Features Before Interview for both Interviewed and Non-interviewed Students.

Feature	Interviewed			Not interviewed		
	N	Pre	During/Post	N	Pre	During/post
Absolute acceleration (mean)	79	1.31 (2.38)	1.17 (2.86)	194	1.04 (1.15)	1.19 (2.20)
Acceleration (std)	77	8.38 (24.57)	7.83 (26.15)	192	5.26 (12.36)	6.51 (19.02)

Note. β denotes fixed-effect estimates and values in parentheses are standard errors.

use, we included 'tool', 'measure', and other the name of available measurement tools. Because movement patterns cannot be reliably identified in interview transcripts, this analysis was limited to tool use and observation behaviors. After investigating direct attention cue effect, we refit the model in the second analysis (interview reactivity) while excluding interviews containing an attention cue for the target behaviors. This was done to see whether the interview effect is replicated with the condition. By reproducing interview reactivity, we can see whether direct attention cue effect can be divided with other potential mechanisms explaining the interview reactivity. Across all models, camp and world were included as random effects. When model convergence issues occurred, the random effect of camp was removed and the model was refitted.

4. RESULTS

Across the four camps, we collected 120 interviews from 60 students (mean: 2, std: 1.22) from the five target worlds. A total of 33 interviews were excluded because interview time logs (4 cases) or world playtime logs (9 cases) were unavailable; the interviews contained no meaningful content (7 cases), such as when students were chosen but they refused to participate or interviewers terminated the session within 50 seconds; or a student completed multiple interviews within the same world (20 cases), as repeated interviews within a world could distort the defined time frame. After screening the interviews, 87 interviews from 55 students remained (mean: 1.58, std: 0.85). Each camp had an average of 21.75 interviews (std: 8.06). The five worlds included in the analysis had an average of 17.4 interviews each (std: 2.30). The average interview time was 264.16 seconds (std : 117.90) while the average play time before an interview was 621.37 seconds (std : 372.32) and the average play time after an interview start was 653.14 (std : 530.16).

4.1 Behaviors Differences Before Interview

The first analysis examined whether students who were interviewed differed from those who were not interviewed in terms of their behavior or interest at a given time point. Table 2 provides descriptive statistics comparing behavior features for interviewed and non-interviewed students. GLMM models were used to test whether interview status significantly predicted students' pre-interview behaviors and pre-interview interest. In these models, camp and world were included as random effects. The results indicated that interviewed students exhibited significantly higher occurrence of tool use (binary), whereas no other significant differences were observed between the interviewed and non-interviewed groups in either behavioral or interest measure.

4.2 Interview Reactivity

Second, we examined whether interview participation significantly predicted students' behaviors after the interview. GLMM models were fit to compare during/post features while including pre-behavior, whether the student was interviewed or not, their interaction, and pre interest as fixed effect (Table 3).

Significant positive main effects of interviews were observed for several features. Specifically, interview participation significantly predicted the occurrence of observation, and occurrence of tool use. In these models, pre-interview behavior and pre-interview interest were also significant predictors, while occurrence of tool use had significant negative interaction effects. In case of observation occurrence, there is significant interview main effect without interaction effect ($\beta = 1.30$, SE = 0.49, $p = 0.009$). On the other hand, although interview was associated with an increased likelihood of tool use ($\beta = 1.41$, SE = 0.48, $p = .003$), this effect was significantly moderated by pre-interview tool use, as indicated by a negative Interview * Pre tool use interaction ($\beta = -1.65$, SE = 0.64, $p = .010$). This pattern suggests that interview reactivity may be most evident among students who had not used tools prior to the interview. As the main and interaction effects are pointed in different directions in tool use, interpreting the interview effect based solely on the main effect coefficient can be misleading. Therefore, we probed the interaction by examining the conditional pre–post behavioral association among interviewed students (i.e., the combined coefficient $\beta_int + \beta_interaction$). Simple effects analyses showed that interview participation did not significantly affect tool use among students who had already engaged in tool use before the interview ($\beta = 0.24$, SE = 0.42, $p = .57$). Together, these results highlight that students' baseline behavioral status plays an important role in shaping interview reactivity.

Some movement features—including absolute acceleration mean, acceleration standard deviation, and mean distance—showed significant positive interaction effects with interview participation. However, although the corresponding main effects were not statistically significant, they were opposite in direction to the interaction terms. This pattern suggests that the direction and magnitude of interview-related effects may vary depending on students' pre-interview behavioral levels. Overall, post-interview movement patterns remain systematically linked to baseline movement behaviors, implying that interview participation may partially shape subsequent movement dynamics.

For features that showed no interview or interaction effects in the full models, reduced models excluding the interaction term were fitted. However, no additional interview effects were detected for other features.

4.3 Direct Attention Cue Effect

Lastly, we examined whether the observed reactivity in the occurrence of observation and tool use was driven by direct attention cues during interviews. This was achieved by comparing interviews that explicitly mentioned the target behavior with those that did not. In terms of interviews mentioning observation and tool use, 31 interviews included the 'observation' keyword while 30 interviews mentioned tool use keywords (see table 1). We compared during/post features while including pre-behavior, interview mention, their interaction, and pre interest as fixed effect (Table 4). Camp and world were included as random effects across all models.

No significant direct attention cue effects or interaction effects with pre-behavior were observed for either observations or tool use. Since neither feature showed a main or an interaction effect in the full models, reduced models excluding the interaction term were fitted. However, no additional attention cue effects were detected for either observation or tool use.

After examining direct attention cue effects, we re-ran the analyses comparing the behaviors of students who were interviewed to that of students who did not get interviewed (as in section 4.2), this time excluding interviews which explicitly mentioned the target behavior (observation or tool use). These analyses were conducted to assess whether interview reactivity was still significant when only considering interviews that did not include direct attention cues. The results showed that the previously reported effect of interview on the occurrence of tool use and its interaction effect between interview and pre-behavior were fully replicated. In contrast, for the occurrence of observation, the previously identified main effect of interview participation was no longer observed.

Table 4. General Linear Mixed Methods Results (Coefficients, Standard Errors, and P-values) for Direct Attention Cue Models and Interview Effect Reproduction Models Predicting Each of Two Features: The Occurrence of Observation and Tool Use.

Behavior	N	Pre-behv	Interview	Pre-behv * Interview	Pre-interest
Direct attention cue effect					
Observation (occurrence)	47	β = 1.42 (0.83) p = 0.085	β = 1.48 (1.38) p = 0.282	β = -2.28 (1.58) p = 0.149	β = 0.14 (0.24) p = 0.564

Reproduction of interview effect without interview mention					
Observation (occurrence)	257	β = 1.88 (0.42) p = <.001	β = 1.11 (0.52) p = 0.035	β = 0.16 (0.73) p = 0.821	β = 0.15 (0.12) p = 0.187
Tool (occurrence)	246	β = 1.10 (0.39) p = 0.005	β = 1.43 (0.53) p = 0.006	β = -2.14 (0.77) p = 0.006	β = 0.33 (0.12) p = 0.007

Note. β denotes fixed-effect estimates and values in parentheses are standard errors.

5. DISCUSSION AND CONCLUSION

This study examined whether and how data-driven classroom interview (DDCI) influences students' behaviors in a game-based learning context, by comparing a range of in-game behaviors of students following their interviews to the behaviors of students who were not interviewed. Specifically, we investigated behavior differences related to the use of in game observations, scientific measurement tools and movement-related behaviors. The results indicate that DDCI does exert an influence on learners' behaviors; however, this influence is selective rather than uniform across all behavioral features.

First, the occurrences of tool use and observation, two core inquiry behaviors in WHIMC, were positively influenced by interviews. This suggests that rather than distracting students from the learning activity, students may become more engaged in inquiry processes within the game environment following interviews. This finding aligns with the metacognitive reactivity described by Bosch et al. [3], highlighting DDCI's potential to exert positive influences on students.

However, while students showed increased occurrences of tool use and observation following interviews, no significant interview effects and a few interaction effects were found for movement features. Reactivity in in-game observations and scientific measurement tool uses are particularly meaningful because they reflect intentional, goal-directed actions that learners may consciously engage in, in contrast to movement-related features that are more likely to emerge as byproducts of task engagement. This indicates that characteristics of each behavior such as intentionality or goal-direction may influence the impact of DDCI, as suggested by Double and Birney [4] that task characteristics influence how reactivity operates cognitive and metacognitive processes.

Even reactivity within a single behavior should be examined carefully, as it may involve complex underlying mechanisms. In our findings, interview reactivity predicted the occurrence of tool use and observation, but not the frequency of these behaviors. Even these occurrence-level effects were conditional: reactivity depended on students' pre-interview behavior and was most pronounced among those who had not engaged in tool use prior to the interview. Together with other interaction effects for movement-related features in this study, these results suggest that reactivity is not uniform but varies according to individuals' prior states [4]. This variability and complexity indicate that researchers should not conceptualize reactivity as a simple yes-or-no phenomenon, but rather as a multifaceted process shaped by the interplay of task characteristics and individual-level factors.

The mechanisms underlying the reactivity can be interpreted in multiple ways. In the present context, all students were aware of the presence of observers and interviewers; nevertheless, significant behavioral differences emerged between interviewed and non-interviewed students. This finding suggests that the effects observed cannot be explained solely by a general observer effect, but rather that the interview process itself is a contributing factor.

Research on verbalization reactivity supports this interpretation. Studies on think-aloud and verbal reporting have demonstrated that while spontaneous inner thought verbalization tends not to affect performance, higher-level verbalization—such as describing and explaining one's current thoughts and actions—can be reactive [5, 7, 8]. In the present study, while our interviewers attempted to minimize disruption to learners' ongoing activity by avoiding retrospective questions and instead asking students to describe what they were currently doing, responding to such prompts might still require learners to articulate and reflect on their ongoing behavior. Within Ericsson's framework, this constitutes a form of reactive high-level verbalization, which may activate metacognitive processes by encouraging learners to reflect on their actions.

However, inconsistent with this interpretation, the present study didn't identify attention cue effect described in the metacognitive reactivity framework proposed by Double and Birney [4]. No direct attention cue effect was revealed. Also, while interview reactivity was reproduced even without interviews mentioning the behaviors for the occurrence of tool use, this effect was not reproduced for the occurrence of observations. The success to reproduce reactivity of tool use occurrence suggests that the reactivity of tool use might be independent from attention cue effect. On the other hand, failure to reproduce reactivity of observation occurrence suggests either a broader form of attention cueing that is not captured by explicit behavioral mentions alone, or insufficient statistical power due to the small sample size to detect differences between cueing and non-cueing interviews.

These results may also reflect limitations in how attention cues were operationalized in this study. Rather than conducting a detailed analysis of interview content, we used a simple keyword matching approach to identify whether a given behavior was explicitly mentioned in an interview (e.g. mention of 'observation' or 'tool'). It is possible that relevant behaviors were implicitly discussed without the use of specific keywords. For example, in the case of tool use, interviews may have referenced phenomena (e.g., windy area) or interpretations derived from tools without explicitly mentioning the tools themselves (e.g., 'airflow'). Such instances were not systematically captured in the present analysis, which may have attenuated the attention cue effects. More fine-grained analyses of interview content are therefore needed to better understand the mechanisms of DDCI reactivity.

Given that both the present study and prior research [3] consistently indicated that students are likely to be reactive to DDCI, a critical methodological question concerns how such reactivity should be addressed. While traditional methodological perspectives have emphasized minimizing or eliminating reactivity [15], more recent work has advocated for a reactivity-transparent approach, in which

reactivity is explicitly examined, documented, and analytically incorporated rather than treated solely as a source of bias [17, 34]. As DDCI enables the collection of ecologically valid data within authentic learning contexts, understanding how DDCI-induced reactivity influences research findings is essential to fully utilize DDCI's power.

Researchers need to clarify what aspects of learners are influenced, how they are influenced, and when such influences occur. Beyond identifying the existence of reactivity, it is also critical to evaluate its implications for specific research questions. The same reactivity effect may have different consequences depending on the research objective. For example, when the goal is to model interest based on behavioral log, changes of their actual behavior may not substantially distort the results, and this can be tested by validating the model in another context. In contrast, when the research objective is explanatory—such as examining relationships among behaviors—asymmetric reactivity effects across behaviors may bias estimated relationships and lead to misleading conclusions.

Researchers should also consider how to mitigate or account for reactivity effects analytically. If reactivity primarily alters the overall occurrence of behaviors symmetrically across behavioral categories and individuals, normalized analytic approaches may help alleviate its impact [16]. For example, Epistemic Network Analysis (ENA), which emphasizes the relative weights of connections rather than raw behavioral frequencies, can reduce sensitivity to differences in behavioral volume across units. However, such approaches are less effective if reactivity alters the way behaviors are externally manifested, rather than merely their frequency.

Methods for the detailed analysis of students' behavioral log data, such as the one developed by the educational data mining (EDM) community, can contribute to revealing more fine-grained measurement about reactivity and suggesting good ways to address it analytically. By leveraging the richness of behavioral log data and feature engineering techniques, researchers can move beyond treating reactivity as a uniform source and instead examine how it manifests selectively across different behavioral dimensions. In the present study, the use of multiple engineered features enabled us to identify asymmetric reactivity patterns in detail. More broadly, methodological approaches developed in the EDM community may provide analytic strategies which account for the influence of students' reactivity to DDCI on the interpretation of student behavior patterns.

Although this study is among the relatively few to empirically examine reactivity associated with DDCI, it remains limited in scope, focusing on a restricted set of behaviors within a specific learning context. This limitation highlights the need for future research examining DDCI reactivity across diverse contexts and outcome measures, including behavioral, affective, and metacognitive indicators. Additionally, variations in reactivity across demographic groups should be considered, as certain groups may perceive greater levels of surveillance from interviewers. As such evidence accumulates, the role, strengths, and limitations of DDCI as a research instrument can be more clearly articulated. A similar process has unfolded in the development of think-aloud protocols. Since their introduction over three decades ago, think-aloud methods have been subject to sustained debate regarding their identity and reactivity. Through extensive empirical use, meta-analyses, and methodological debate, researchers have developed refined protocols aimed at minimizing reactivity and clarifying appropriate use cases [5–8, 28]. These findings played a central role in differentiating the method from other methods and in establishing empirically grounded guidelines for managing reactivity.

Similarly, DDCI requires sustained empirical investigation and cumulative synthesis to clarify its identity, strengths, and limitations relative to other research instruments. Beyond investigating how the interviews contribute to students' reactivity during DDCI, future work should also examine how other components of the DDCI method, such as variations in interview length, interview triggers design or the interview prioritization algorithm, may impact student reactivity. Through such efforts, DDCI can be more rigorously positioned as a research tool, with its methodological affordances and constraints clearly understood.

ABSTRACT

The prevalence of online reading platforms has surged along with improvements to automatic speech recognition (ASR) systems. These platforms facilitate personalized reading instruction, but like all learning systems, work best when students find them engaging. The Educational Data Mining (EDM) community has made great efforts to detect student engagement, but these efforts have largely been confined to school and lab environments without intentionally including neurodiverse populations. In the present study, we evaluate engagement levels in children with attention deficit hyperactivity disorder (ADHD, n=55), autism (n=38), both autism and ADHD (n=38) and with no known clinical diagnoses (n=22) as they interact with a digital literacy learning system from their homes. Engagement was measured using parent report, and acoustic features were extracted from audio recordings of the students while they interacted with the Amira literacy learning system. Our results indicate that acoustic measures related to temporal features, pitch, and vocal quality are related to engagement levels across all clinical groups. We also identify key temporal features that vary across different clinical groups. These findings demonstrate the validity of using non-invasive acoustic features to measure engagement levels during reading comprehension tasks at home. However, interaction effects also highlight the importance of taking into account children's clinical diagnosis when measuring engagement.

1. INTRODUCTION

Digital reading platforms have emerged as a promising way to provide personalized literacy instruction to students, both at home and at school. These platforms guide the student through level-appropriate passages where they can read text out loud, receive real-time interventions, and respond to reading comprehension questions[69]. Compared to traditional instruction, Intelligent tutoring systems (ITSs) for reading can even produce larger learning gains [65, 70], even among students with learning differences that sometimes interfere with reading comprehension, such as Autism Spectrum Disorder (ASD) [39]. However, meta-reviews of literacy applications have demonstrated that they are most effective when (1) the systems are highly interactive and (2) children use them with higher intensity (at least 75 minutes per week) and duration (at least 3 months) [39, 69, 70]. This leads to a direct need to understand how engaged students are with a platform in order to provide effective instruction and keep them coming back for regular sessions.

Reading engagement is often defined as the student's active involvement with reading [32], and it is sometimes distinguished from motivation by considering motivation as a mindset that is necessary in order to deeply engage with reading [2]. Although exact definitions of reading engagement vary, it is often described as including cognitive, affective, and behavioral dimensions [41]. Reading engagement is not only indicative of children's enjoyment, but is also linked to improved reading abilities and reading comprehension [6, 31, 41, 63].

Despite an abundance of research on engagement measures, there is no standardized method for measuring student's engagement with online reading platforms. Some conversational agent based literacy tools operationalize verbal engagement in terms of child response length [33] or semantic features including topic relevance and intelligibility [68]. However, these measures are proxies for the actual construct, which is likely to involve a range of cognitive, behavioral, and affective experiences [26]. Moreover, they do not account for key acoustic elements, including those that may be more in-

dicative of a students' affective experience with the reading activity [44].

In this study, we explore the use of acoustic features to detect reading engagement among neurodivergent students with different clinical diagnoses, including Autism and Attention Deficit Hyperactivity Disorder (ADHD). We examine the use of acoustic features as they can be easily extracted by voice-based reading software without the use of specialized equipment that may be difficult to acquire for use in either the home or classroom. We evaluate the interaction between clinical diagnosis and engagement levels by analyzing acoustic features that indicate voice quality, speaking rates, and prosody, and which have been associated with engagement in prior research [34, 44].

To our knowledge, this is one of the first studies to focus on understanding which acoustic features most effectively model engagement during digital reading instruction, and one of the first in the EDM community to consider how clinical diagnoses might affect those modeling efforts. Our results indicate that temporal acoustic features are robust indicators of engagement across groups in our study, but other acoustic features (e.g., variation of voiced segment length) are diagnosis-sensitive. With this work, we aim to contribute to a better understanding of how engagement manifests differently in diverse populations of learners while also putting forward tools to help detect these differences, provide personalized support, and ultimately improve outcomes.

2. BACKGROUND AND RELATED WORK

Research on student engagement defines it across many dimensions, including behavioral, emotional, and cognitive domains [26]. Real-time models of student engagement have become a common way for researchers in the Educational Data Mining community to study engagement at scale, including both affective engagement and cognitive engagement. Such models have been trained on a variety of label types, including those produced from text-based video [76], video data [10, 36], speech [71, 44] physiological signals including skin conductance data [12, 77], posture data [56], and self-report [74, 18]; and from classroom observations [5, 50].

Much of this work has focused on affective engagement [13], although behavioral and cognitive engagement [30, 42] are also modeled. Such models have been particularly important for researchers studying affect dynamics [20, 51]. They have also been useful for making short-term and long-term predictions about student learning outcomes [27]. However, given the rich history of definitions involved with studying student engagement in the broader research community [26], the EDM community continues to explore novel ways to capture this construct.

2.1 Detecting Reading Engagement in Learning Systems at Home

One particularly difficult challenge in this space is appropriately creating high quality engagement labels for students who use learning software at home. Many sensors used to detect engagement can be highly invasive (e.g., video), while others are difficult to use in the home environment (e.g., posture sensors). Meanwhile, interaction-based detectors [50] rely on classroom observation or self-report data to provide the labels. Although these detectors can certainly be applied to students in the home environment, it is difficult to verify whether detectors trained on labels from a classroom environment would generalize to students' home environments. Additionally, self-reports are susceptible to self-presentation effects and to differences in students' ability to gauge their own level of participation [21, 28].

A few studies have sought to leverage measures that could be more easily collected in a home environment. For example, models based on student response times leverage item response theory to distinguish between engaged and disengaged students in online settings [7, 35]. These could be used in home environments, even if they might need to be renormed for different clinical populations. Another approach is to measure student talk time while engaging with an online tutor[17]. Some existing reading software measures verbal engagement based on the number of turns with a conversational agent or word counts [33]. Xu et al. [68] evaluated the nuances of children's responses to comprehension conversations asked by conversational agents versus humans via five aspects of verbal engagement: lexical diversity, intelligibility, productivity, topic relevance, and accuracy [66, 64]. Similarly, Gorgun et al. leveraged linguistic features in online discussion posts to estimate engagement based on third-party manual coding [30]. Their scheme defined four attributes of cognitive engagement: interactive, constructive, active, and social.

In addition to semantic-based engagement features, some researchers have explored the use of acoustic features in the online setting. Litman et al. [44] evaluated prosodic cues of disengagement and uncertainty while students engaged with a physics tutor. Their research demonstrated that when students are disengaged, they respond significantly more slowly than engaged students. Disengaged students were also found to have lower maximum and mean pitch values than their engaged peers. Furthermore, disengaged students demonstrated more steady pitch values as well as lower levels of energy. Our study builds upon these findings, with the intention of exploring whether they apply to non-neurotypical learners.

2.2 Reading Engagement in Individuals with ASD and ADHD

As our ability to detect engagement in online settings has advanced, there have been increasing calls for better understanding for a more diverse range of learners [52], and subsequent research has shown that additional demographic information can improve models. For example, Karumbaiah et al. [38], shows that some behavioral engagement measures (i.e., help-seeking) are better understood when school-level demographics are taken into account. Likewise, other research has shown that we can improve our models of mind-wandering by accounting for neurodivergence [67].

Accounting for clinical diagnoses in engagement research is particularly important since certain conditions are characterized by developmental challenges that begin to emerge during early childhood and impact multiple life domains (e.g. school, home) across the lifespan [49]. These increasingly prevalent conditions are characterized by factors that

Table 1: Demographic and clinical characteristics of participant groups. Number of activities signifies the number of comprehension conversations that were included from each participant subset.

Clinical Group	Mean Age (SD)	Male	Female	Ethnicity	Activities
ADHD	8.527 (1.386)	35	20	Not Hispanic or Latino (48)	305
				Hispanic or Latino (7)	
ASD	8.345 (1.632)	14	15	Not Hispanic or Latino (22)	129
				Hispanic or Latino (7)	
ASD+ADHD	8.316 (0.904)	22	16	Not Hispanic or Latino (34)	169
				Hispanic or Latino (4)	
Not ASD or ADHD	8.409 (1.054)	11	11	Not Hispanic or Latino (18)	103
				Hispanic or Latino (4)	
Overall	8.417 (1.276)	82	62	Not Hispanic or Latino (122)	709
				Hispanic or Latino (22)	

could interfere with our measurement of student engagement [14]. For example, individuals with Autism Spectrum Disorder (ASD) face persistent challenges in social communication, as well as restricted or repetitive patterns of behaviors, interests, and activities [4]. Attention-deficit/hyperactivity disorder (ADHD) is a neurodevelopmental condition diagnosed in about 1 in 11 (10.5%) of U.S. school-aged children [15] and is distinguished by persistent patterns of inattention and/or hyperactivity-impulsivity. While autism and ADHD are distinct neurodevelopmental conditions, they frequently co-occur. 50-70% of people with ASD meet diagnostic criteria for ADHD [58] and 12.5% of individuals with ADHD meet diagnostic criteria for ASD [73]. This co-occurrence (colloquially referred to as AuDHD) could result in additional nuances in learning behavior that would further complicate accurate measurement of engagement in this population.

Although ASD and ADHD often co-occur with disabilities that directly impair reading skills (e.g. dyslexia; [11]), various clinical features specific to ASD and ADHD can also contribute to challenges with reading engagement and comprehension for children with either condition. Specifically, impairments in social communication, word recognition, and oral language may compromise many autistic children's reading comprehension skills [57, 46, 40]. Furthermore, some early autistic readers exhibit a striking discrepancy between their reading comprehension and word recognition skills such that their reading comprehension skills lag behind their growing proficiency in word recognition [16]. Reading comprehension may also pose difficulty for children with ADHD. Working memory impairments that are characteristic of ADHD can constrain reading comprehension and limit children's ability to recall central ideas from text directly after reading it [47]. Additionally, on average, children with ASD and/or ADHD may struggle to maintain sustained attention on tasks they are not interested in or motivated to complete. This suggests that children with ASD and/or ADHD may exhibit reduced engagement when reading texts they did not choose [37] or that is not related to their interests [22]. Thus, several clinical characteristics associated with ASD and ADHD may exert a powerful influence on reading engagement and comprehension. With the rising use of digital literacy platforms aimed at supporting children's reading skills, there is a critical need to accurately measure how children with ASD and/or ADHD engage with and comprehend the texts they read on these platforms.

3. PRESENT STUDY

3.1 Digital Literacy Platform

Amira [1] is an online, AI-powered reading platform that delivers real-time, adaptive literacy instruction. The virtual tutor,named Amira, listens to students as they read aloud, identifies reading miscues or skill gaps, and provides brief, real-time instructional supports (micro-interventions) aligned to the Science of Reading and tailored to the student's ability level and performance history. During comprehension dialogue activities, Amira prompts students with questions designed to assess and deepen skills that are aligned to grade-level Reading Comprehension standards. For students in grades 3 and above—where the cognitive and language demands are appropriate—Amira may initiate a comprehension dialogue micro-intervention rather than using the traditional multiple-choice format. These dialogues use open-ended prompts to probe the student's ability to demonstrate the skill, capturing explanation, reflection, or elaboration. Dialogues are modeled after authentic classroom questioning. The student responds either orally or by typing a response, and Amira uses advanced speech recognition and natural language processing (NLP) to capture and compare student responses against a detailed pre-defined rubric.

Each conversation can extend up to two turns of dialogue. The dialogue follows the structure of an opening prompt from the tutor, student response, a follow-up tutor prompt, student response, and final tutor response. A response timer is activated after the initial prompt is delivered, and students are given 10 seconds to begin their response to that turn. If no response is detected within this timeframe, the system will automatically deliver scaffolded support (a hint and a re-prompting of the same question). If any response attempt is detected, the student has 60 seconds in total to respond to the prompt on each turn. There is a visual timer present during the interaction to convey this per-turn time limit. The follow-up prompt is intended to scaffold the student towards further addressing rubric criteria that they did not adequately cover in their initial answer.

All response data—including ASR transcripts, timing, accuracy of the response based on the skills being taught, and behavioral markers such as hesitation or repetition—is logged for subsequent analysis, enabling researchers to investigate both dialogue engagement and comprehension skill performance within a dialogic reading context. For this study, we focus solely on the audio recordings and transcribed stu-

Table 2: Subset of acoustic features from eGeMAPS [23] use in analysis grouped by category.

Domain	Features
Temporal	Loudness Peaks Per Sec; Voiced segment length (s: mean, std. dev.); Unvoiced segment length (s: mean, std. dev.)
Energy	Harmonic-to-Noise ratio (mean, std. dev.)
Frequency	Fundamental Frequency (F0: mean, std. dev., 20th, 50th, 80th percentiles); F0 mean rising slope; F0 mean falling slope; jitter (mean, std. dev.)
Spectral	Alpha ratio, voiced (mean, std. dev.); Alpha ratio, unvoiced (mean); Hammarberg index, voiced (mean, std. dev.); Hammarberg index, unvoiced (mean, std. dev.); Spectral flux, voiced (mean, std. dev.); Spectral flux, unvoiced (mean); Spectral slope 0–500 Hz (mean, std. dev.); Spectral slope 500–1500 Hz (mean, std. dev.)

dent responses from the comprehension dialogues described above.

3.2 Methods

3.2.1 Participants and Data Collection

Participants who consented to be contacted for research studies were recruited via the Center for Autism Research (CAR) at the Children's Hospital of Philadelphia (CHOP). CHOP's Electronic Health Records (EHR) database. 1000 emails per week were sent out to CHOP patients based on certain selection criteria, including (a) diagnosis of autism spectrum and/or attention deficit/hyperactivity spectrum disorder or not, (b) age 5-12 years, and (c) in the "learning to read" phase according to parent report. 144 children aged 5-12 years with a diagnosis of autism (N=29), ADHD (N=55), autism + ADHD (N=38), or no diagnoses of autism or ADHD (N=22) consented to participate in a 7-week at-home reading intervention pilot study. Once enrolled, participants were instructed to read four to five stories per week on Amira , or for at least 30 minutes. Caregivers completed surveys providing basic demographic information and feedback on their child's experience with Amira. Full demographic details for participants can be seen in Table 1. This study was overseen by the Institutional Review Boards at CHOP and MDRC.

3.2.2 Acoustic Features and their Extraction

For each of the comprehension activity turns, we extract acoustic features based on the extended Geneva Minimalistic Acoustic Parameter set (eGeMAPS) [23] using the OpenSMILE toolkit[25]. eGeMAPS is considered a high quality acoustic feature set for use in emotion recognition tasks [19], which are closely related to the engagement identification question. eGeMAPS consists of 25 low-level acoustic features comprising four key categories related to these tasks: prosody, temporal, pitch, and spectral features. Acoustic features are extracted at regular intervals (e.g, every 10 ms) from speech samples and the resulting feature time series is mapped to fixed-dimensional feature vectors by applying one or more statistical functions (e.g., mean, standard deviation, percentiles), resulting in 88 features[1] for each student response turn. For frequency values, we focus solely on the fundamental frequency F_0 which has been used in prior studies as a measure of distinguishing pitch values between neurodivergent and neurotypical students [53]. This results in a subset of 49 acoustic features that we use for our analysis as seen in Table 2.

Table 3: Breakdown of the study dataset based on values with the parent-reported engagement labels: not engaged (NE), Somewhat Engaged (SE), and Very Engaged (VE). Only students with audio recording files are included in the count.

Clinical Group	Not Engaged	Somewhat Engaged	Very Engaged
ADHD	1	17	26
ASD	0	8	13
ASD+ADHD	1	12	8
Not ASD or ADHD	0	4	8

Prosodic features attempt to characterize the expressive qualities of speech including voice quality, rhythm, and intonation that convey emotion and emphasis; examples include jitter, shimmer, and harmonic noise ratio measures.

Frequency features attempt to characterize how high or low the voice sounds and how it varies over time, capturing both the fundamental frequency (F_0, perceived as pitch) and the resonant frequencies of the vocal tract (formants). As mentioned above, we only analyze fundamental frequency values in this work. These features were crucial in the work of Litman et al. [44] which showed that pitch was statistically significant for discriminating between engaged and disengaged students.

Temporal features attempt to characterize speech timing, including speaking rate and pause frequency. We consider the rate of speech, number of pauses based on loudness values, and variations in voiced and unvoiced segment lengths, which have been used in prior work discriminating between student engagement levels [44].

Spectral features are features that correspond to the spectral shape, such as slope, which are frequently used for affect recognition [23, 61]. These also include the first four Mel-Frequency Cepstral Coefficients (MFCCs), which have a documented association with valence and level of interest [24].

For further details regarding feature extraction (e.g., frame step, window size, MFCC filterbank/DCT parameters, functionals applied to each acoustic feature), consult [19] and [23].

3.2.3 Parent Reported Engagement (PRE) Labels

Following seven weeks of the at-home intervention, parents were given a survey to gather information about their child's

[1]Not all statistical functions are applied to all low-level acoustic features.

experience with the literacy learning system. This survey included a specific question about how engaged their child was while interacting with the tutor with three possible values: *Not Engaged*, *Somewhat Engaged*, and *Very Engaged*. This measure, which we will refer to as the parent-reported engagement (PRE) label, represents a relatively basic measure of engagement, as it does not ask parents to distinguish between the various ways in which engagement might manifest. However, it represents a valuable perspective on engagement from caregivers who are most familiar with the participants' unique focus styles and avoids concerns about the reliability of children's self-report data [21, 28].

PRE was provided by the parents of 139 participants, with 98 of those participants having audio recordings available for comprehension conversations. Labels were highly skewed towards the *Very Engaged* and *Somewhat Engaged* values with only 4 participants reported as *Not Engaged* during the sessions, only two of whom had audio recordings. As such, any patterns observed involving the Not Engaged group should be considered exploratory. The full distribution of clinical diagnosis based on engagement level can be seen in Table 3. We exclude any students who have fewer than two audio recordings present in the data. We apply the parent-reported engagement (PRE) level as a measure of overall engagement propensity to all comprehension activities with audio recording for the student. This is not intended to indicate turn-level engagement, but instead enable us to identify what acoustic features are correlated with children's general engagement statement.

3.2.4 Data Preprocessing

We conducted a series of preprocessing steps. In order to ensure that each participant had enough acoustic data for analysis, we first selected for students who had participated in at least two comprehension activities. We then aggregated all of the comprehension conversation turns for that student and aligned them with the appropriate audio file. Acoustic features were extracted using the OpenSMILE [25] toolkit for each of the student conversational turns. We collected system-generated transcriptions of student responses, which were processed through a simple word count function to generate verbal response counts for each turn. We then align the transcribed student response data, audio files, and the demographic and engagement reports from the parent surveys[2].

3.2.5 Measuring the Effect of Diagnosis x Engagement

To examine effects of clinical diagnosis and PRE levels on acoustic features while accounting for the fact that we have multiple audio recordings for each child, we employed population average models using generalized estimating equations (GEE). GEE models are well-suited for correlated data and provide robust inference without requiring explicit modeling of subject-specific random effects [43, 59, 75]. We also explored the use of mixed-effect models; however, they could not be applied across all the desired acoustic features due to limited within-child variability.

[2]The resulting dataset will be released for future work following the completion of the requisite anonymization process.

Table 4: Number of acoustic features showing significant population-level effects after FDR correction, stratified by feature category and predictor.

Feature Category	Diagnosis	Eng.	Diagnosis × Eng.
Energy	0	3	3
Frequency	0	6	8
Spectral	0	14	27
Temporal	0	2	5
Total	**0**	**25**	**33**

For each acoustic feature mentioned above, we fit a Gaussian GEE of the form:

$$\begin{aligned} Feature_{ij} = \beta_0 + \boldsymbol{\beta}_1^\top \text{Diagnosis}_i + \beta_2 \text{Engagement}_i \\ + \boldsymbol{\beta}_3^\top \left(\text{Diagnosis}_i \times \text{Engagement}_i\right) \\ + \beta_4 \text{Age}_i + \beta_4 \text{Sex}_i + \varepsilon_{ij}. \end{aligned} \quad (1)$$

where i represents children and j represents individual acoustic observations. Individual acoustic observations are represented by a vector of acoustic features from OpenSMILE that were extracted from a single turn in the comprehension dialogue. These models included clinical diagnosis, engagement, and the interaction of diagnosis and engagement as categorical predictors, with child age (mean-centered) and sex (parent-reported assigned sex at birth) as covariates. They were fit using the python *statsmodels* package [60] with the correlation structure set to exchangeable to account for the within-child correlation from the repeated observations [43]. Given the broad range of values for different acoustic features, we normalized the values using *StandardScaler* from *scikit-learn* [55]. We also use the *statsmodels* package to account for possible false-discovery rates (FDR) for diagnosis, engagement, and interaction effects with the Benjamini-Hochberg false discovery rate procedure [8] with adjusted p-values set using the methodology defined by Yekutieli and Benjamini [72].

4. RESULTS

We examine the results of fitting a GEE model across the 49 acoustic features in Table 2 as well as the verbal response count of the student responses. In Table 4, we present the acoustic features that are the most impacted by engagement, diagnosis or the combination of diagnosis and engagement. The parent-reported level of engagement acts as an independent predictor of acoustic features across all the categories. There were no statistically significant diagnosis-related effects present in the dataset. The interaction effects of diagnosis and parent-reported engagement are distributed across all of the feature categories.

4.1 Verbal Response Count

Table 5: GEE Results for Verbal Response Count. This table shows the FDR-adjusted p-values across all model terms. None of the values were considered statistically significant.

Predictor	FDR-adjusted p-value
Diagnosis	0.0627
Engagement	0.2420
Diagnosis × Engagement	0.2998
Age	0.1256
Sex	0.3986

In alignment with prior work in verbal engagement, we created a GEE model for the normalized verbal response count. This is taken as the count of words from the transcribed student response for a single turn. The results are displayed in Table 5. Our findings demonstrate that there was no statistically significant impact of engagement, diagnosis, or the interaction of the two on this metric. This suggests that this feature is not dependent on any of these categories.

4.2 Effect of Age and Sex on Results

We account for variations in age and sex in our results by adding them as intercepts to the GEE model. The results that we report for all engagement, diagnosis, and their interaction are those that did not have a statistically significant influence from these variables. Of the 49 acoustic features evaluated, only one had a statistically significant association age: the standard deviation of jitter. Mean child age had a positive coefficient of 0.101, indicating that as children get older than the mean age (in our case 8.4 years old), their variability in jitter levels increased as well. Child sex (as reported by parents in the demographic survey) did not have a statistically significant association with any of the acoustic features tested.

4.3 Engagement Effects

The GEE model shows that PRE levels have an effect on three *energy*-related features (i.e., shimmer, mean Harmonic-to-Noise Ratio and standard deviation of the Harmonic-to-Noise Ratio). PRE also impacts a number of *frequency* features (e.g., those related to the pitch based on F_0 semitone values and jitter, and changes in consecutive F_0 frames) and *spectral shape* features (e.g., Alpha Ratio, Hammarberg Index, and Spectral Slope values). In addition, PRE affects both the mean values of voiced segment length as well as loudness peaks per second - both of which are associated with speaking rates. These findings are consistent with prior work evaluating fluctuations in acoustic features related to arousal, engagement, and emotion [3, 7, 24, 44]. The majority of the contrast effects for the model appear between the *Not Engaged* and *Very Engaged* groups, however, we do see a meaningful difference between shimmer values for the *Somewhat Engaged* and *Very Engaged* groups. Students in the Somewhat Engaged groups (regardless of clinical diagnosis) exhibited higher mean values of shimmer than those in the Very Engaged group.

4.4 Diagnosis Effects

The GEE analysis of our data did not result in any statistically significant effects for diagnosis as an independent predictor. These findings are surprising given a large body of existing research that demonstrates noticeable differences in prosody, pitch, and voice quality for individuals with autism spectrum disorder vs. neurotypical peers [9, 48, 53, 54]. It is possible that no differences were detected in this study due to high variability in the speech characteristics of individuals with a given diagnosis or the fact that this sample was collected in a highly constrained (and non-social) context. There are still context-dependent diagnostic differences within the dataset that vary based on the child's parent-reported engagement level.

4.5 Diagnosis x Engagement Effects

As shown in Table 4, thirty-three acoustic features exhibited significant interactions between clinical diagnosis and PRE, indicating that diagnostic differences in vocal production depended on PRE. Multiple acoustic categories showed interaction effects, including three associated with *energy*, eight associated with *frequency*, twenty-seven involved with *spectral shape*, and five involved with *temporal values*. Of these features, 18 of them demonstrated an interaction effect without the presence of a statistically significant effect from one of the other predictors. We report the full set of the interaction effects in Table 6. Notably, features related to pitch distribution, spectral variability, and voice quality showed the strongest evidence of context-dependent diagnostic effects, underscoring the importance of considering engagement state when interpreting acoustic markers of clinical diagnosis in educational interactions. The contrast effects referencing Not Engaged in the term should be interpreted as exploratory since there were only 2 students in the analyzed data with audio recordings at this engagement propensity level. Coefficients and patterns reported for the Somewhat Engaged level are representative of a more substantial number of participants and observations in the dataset.

4.5.1 Energy

All three of the features in the energy category demonstrated interaction effects: the mean Harmonics-to-Noise (HNR) ratio and the standard deviation for the shimmer values. However, none of the individual contrast effects between groups registered as statistically significant. There are still some trends that are present in the dataset that should be mentioned for future exploration. Autistic children who were more engaged exhibited higher values of HNR whereas the neurotypical group had the opposite pattern. As seen in Figure 3, For HNR, the ADHD and ASD + ADHD groups more closely resemble the pattern exhibited by neurotypical children, with both showing lower values when Very Engaged vs. Somewhat Engaged. When children in the ADHD and ASD+ADHD groups are rated as Not Engaged, the HNR values are dramatically lower than for the mid-level of engagement, but there is high variability in these groups. This finding is harder to interpret given that there are a very limited number of samples in the dataset with the Not Engaged label. From a practical perspective, when HNR is higher it is indicative of clearer phonation [3] — which means that children with ASD are pronouncing words more clearly when more engaged whilst the other groups are actually reducing their clarity.

We also see opposing patterns between the neurotypical and ASD groups for the shimmer feature. The standard deviation for shimmer is lower for more engaged neurotypical children, whereas it is higher for more engaged ASD children. The more-engaged ADHD group shows a slight increase in shimmer values. Higher shimmer values mean that there is more intensity variability, which is frequently associated with high arousal emotions and higher levels of stress [3].

4.5.2 Frequency

Variations in the frequency characteristics of speech are highly indicative of individual's arousal levels and engagement [3, 23, 44]. In Figure 4, we can see the difference in mean values

Table 6: Acoustic features that exhibit a statistically significant contrast effect (after FDR) based on the interaction of diagnosis × engagement. The reference group for the clinical diagnosis is always *Not ASD or ADHD* and for engagement it is always *Very Engaged*, not engaged is represented as NE and somewhat engaged is represented as SE. Cells show GEE coefficient (Standard Error). * indicates $p < .05$. Dashes indicate non-significant contrasts. † indicates contrast excluded due to anomalous SE = 0. All values rounded to 4 decimals.

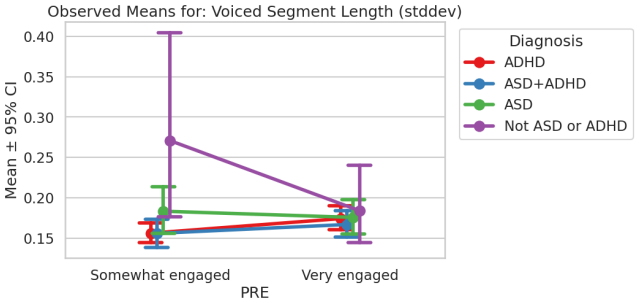

Figure 1: Observed means of the variations of standard deviation in voice segment length across different clinical diagnoses and parent reported levels of engagement.

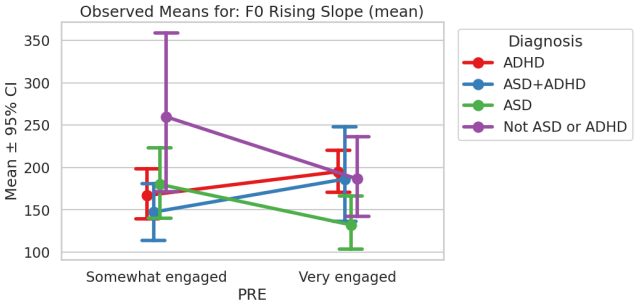

Figure 2: Diagnosis-group level means of the of F0 rising slope across different clinical diagnoses and parent reported levels of engagement.

for the rising slope for F_0 across different clinical diagnoses and engagement values. The neurotypical group exhibits a higher range of values than all of the neurodivergent groups when rated as Somewhat Engaged. These values increase between the Somewhat and Very Engaged groups for individuals with ADHD or ASD+ADHD, but they decrease for neurotypical participants. Essentially, this is indicating that when individuals with ADHD are more engaged they raise their pitch more quickly, whereas the neurotypical students will drop the rate of pitch change when more engaged.

We also notice a stark contrast between the trends of mean values for jitter between the participants with ASD when compared to all other children. Jitter values are higher for Very Engaged ASD children than the Somewhat Engaged group. The pattern is flipped for neurotypical, ADHD, and ASD+ADHD children. Jitter indicates pitch fluctuations in speech and higher values are typically associated with more tremulous or nervous speech [45]. This variation could indicate that individuals with ASD tremble more when they are highly engaged with content than their peers.

For both of these values, the only contrast effect that was statistically significant was for the Not Engaged group with ADHD when compared to the Very Engaged-Neurotypical group. However, given the extremely small sample size of

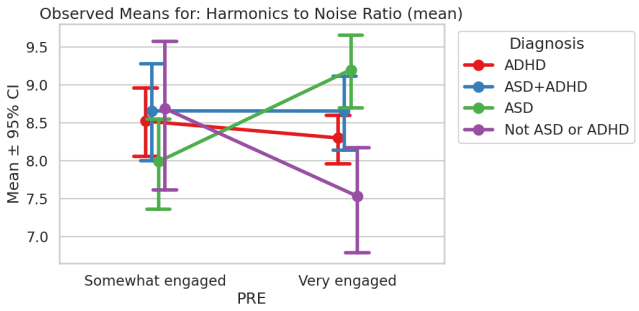

Figure 3: Diagnosis-group level means of the Harmonics-to-noise ratio across different clinical diagnoses and parent reported levels of engagement.

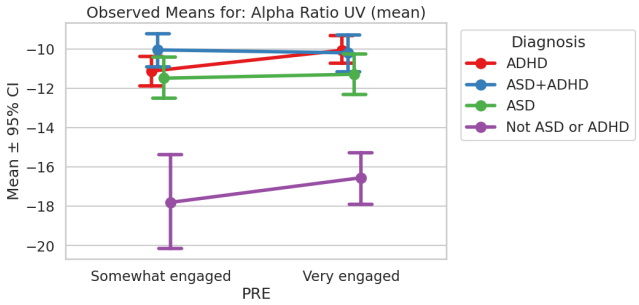

Figure 4: Diagnostic-group level means of the mean Alpha Ratio UV for each of the clinical diagnoses and parent reported levels of engagement.

the Not Engaged group, this result should be verified with a larger dataset.

4.5.3 *Spectral*

Interaction effects are most prevalent for the spectral or vocal shape related features. There are statistically significant effects for the unvoiced Alpha Ratio, voiced and unvoiced Hammarberg Index, MFCC values, spectral Flux and spectral slope values. As seen in Table 9, there are not any statistically significant contrast effects for any of the clinical diagnosis in the Very Engaged group. This means that across the clinical diagnosis, when children were Very Engaged, the spectral shape-related acoustic features appear in a uniform manner in the dataset. On the other hand, there are meaningful contrasts between different clinical diagnosis and the Not Engaged and Somewhat Engaged groups.

In our limited set of Not Engaged participants, we see a number of contrasting acoustic features from the Not ASD or ADHD:Very Engaged reference group. As demonstrated in Figure 4, the ASD+ADHD group had higher values for unvoiced Alpha Ratios than the reference, whereas the ASD group had substantially lower ones. A low Alpha ratio is usually associated with a softer voice. The coefficients for the unoviced Hammarberg Index mirror these results; high Hammarberg indices are associated with a softer voice, whereas lower values would be indicative of a sharper one [62]. This could be indicative of a trend where individuals with ADHD speak in a much softer tone when disengaged, as opposed to disengaged individuals with ASD+ADHD who are talking in sharper tones. Generally speaking, the mean values for the Alpha Ratio of the Not ASD or ADHD groups are considerably lower than they are for all other groups in the study.

We do see significant contrast effects in the Somewhat Engaged groups for some of the MFCC values. This includes lower values for MFCC1V for ADHD children and higher values for MFCC4 for Autistic Students. MFCC1V values are usually associated with variations in spectral tilt, with higher values indicating larger amounts of variation. Instead, for the ADHD children this is saying that there is a limited amount of variation in the spectral tilt when they are Somewhat Engaged.

4.5.4 *Temporal*

All of the temporal features had a statistically significant interaction effect, but only three of them had one without the presence of an Engagement effect. This includes the standard deviation of the voiced segment length as well as the mean and standard deviations of the unvoiced segment length. Lower standard deviations of voiced segment length mean that the speaker is talking with a more regular cadence, usually associated with a confident manner of speaking, whereas higher values can be indicative of hesitant speech [29]. In figure 1, we can see that the neurotypical group shows a much larger decrease in this value between the Very Engaged and Somewhat Engaged participants when compared to the neurodivergent groups. This suggests that neurotypical children will sound more confident when they have higher engagement levels, but this perceived confidence shift may not be reflected in the speech of their neurodivergent peers.

5. DISCUSSION

5.1 Implications for Automatic Detection of Reading Engagement

In highlighting the effects of parent-reported engagement, diagnosis, and their interaction on acoustic features, our ultimate goal is to better inform future models of reading engagement for diverse learner groups. Our results highlight the fact that acoustic features may be a more equitable signal than verbal response count for measuring reading engagement in the home setting. We recommend the use of acoustic features that demonstrate robust effects related to engagement propensity while taking into account interactions between clinical diagnosis and engagement levels. This includes Hammarberg index values, Alpha ratios, shimmer, as well as loudness peaks per second and mean values of voiced segment length. However, all of these values were associated with a statistically significant interaction effect between the diagnosis and PRE. Special consideration should be given when using acoustic features to predict engagement levels for children with ASD. In our data, we notice high variability for a number of acoustic features within this group. This may make it especially difficult to accurately predict engagement levels since there may not be a consistent observable speech pattern.

These findings are intended to be used to create adaptive at-home literacy learning systems. The differences presented in acoustic measures for individuals with ASD or ADHD

are not indicative of a reading comprehension deficit. Nor should they be used as a diagnostic tool. Instead, these should be interpreted as evidence that we need to develop more complex acoustic-feature based predictive models that can account for variations in the presentation of speech-related engagement signals. With effective real-time engagement predictions, it is possible to implement interventions that keep students engaged with reading materials at home, and in turns lead to more opportunities for improving their reading comprehension skills.

5.2 Limitations and Future Directions

The detectors presented here are comparable in performance to a range of others in previous research, but would still benefit from further refinement, particularly from efforts that could expand our data collection efforts. It is important to note that this a sensitivity study on the collected audio data, and we are not evaluating the impact of a particular reading intervention on features related to reading engagement. This is a logical next step in future research studies - leveraging these features as a non-invasive measure of the effect of particular reading interventions on student reading engagement in different subgroups.

Like many studies, this analysis would have benefited from the use of a larger data set. This is particularly challenging because the majority of available speech datasets that might serve as points of comparison–especially those used to identify acoustic features related to engagement–are composed of adult speech samples from extemporaneous speech. In addition to raw frequency differences between adult and child acoustic data, children often exhibit different speech behaviors in extemporaneous speech, and our samples were further constrained by the activities students were asked to perform as part of a task related to learning to reading.

In addition to benefiting generally from a larger sample, we would also benefit from diversifying our sample. Importantly, our current dataset is representative of children with several possible clinical conditions, which allowed us to present findings related to neurodiversity that have been understudied in the EDM community. However, it would still benefit from a more robust sampling of ethnic, socioeconomic, and English language learner status as variation within those diagnoses, as those factors are known to affect students' language patterns.

Future work should also look for ways to improve the granularity of the engagement labels, as the PRE labels were derived from parental evaluations of students' experience with the learning system in its entirety. However, even the most engaged child will not be completely engaged during every lesson, or every turn of that lesson. Ideally, in future experiments we will complement this measure with finer-grained labels, allowing us to develop a more nuanced understanding how students who are highly engaged overall might vary over the course of several weeks while also developing a more nuanced understanding of the acoustic indicators of this engagement. Additionally, we acknowledge that our dataset contained a very small number of students in the not engaged group. Ideally, in a larger sample we would have a less imbalanced set of engagement levels. Such efforts would also substantially improve our predictive modeling of real-time engagement.

Finally, we aim to expand our approach to comprehension conversation data. During a single comprehension activity, the microphone is open for a fixed period of time where the student responds to - at most - two conversational turns. This substantially limits the amount of data that can be collected, as students may be cut off before they are able to fully participate with the task. There may be strategic reasons for the learning system to continue such practices, but it would be good to consider ways in which we might better understand how this constraint affects student engagement, particularly as we seek to use more fine-grained levels than those employed in this study.

Still, the course-grained PRE labels deployed here–in addition to serving as an important step towards better understanding home usage–might also help us to better understand when apparent disengagement at the micro-level may be incidental. For example, they likely indicate a students' overall propensity to re-engage with the learning system, which could be used to help filter more fine-grained, moment-to-moment patterns in order to better understand which students need greater support.

6. CONCLUSION

In this paper, we have explored the use of acoustic features to measure reading engagement during online learning sessions across a diverse learner population. Acoustic features provide a non-invasive manner of capturing critical data related to student behavior and affect while they are working with a digital literacy platform at home. We present the nuances of modeling reading engagement for children with ADHD, ASD, or both based on the unique characteristics of these conditions. Our study includes audio and transcription data collected from 144 children over the course of several weeks who engaged in passage reading and reading comprehension tasks while at home.

Specifically, we use parental reports of engagement (PRE) with the system and clinical diagnosis to create generalized estimating equations (GEEs) for engagement-related acoustic features. We compare the effect of clinical diagnosis, parent report of engagement, child age and sex on a set of 49 acoustic features across 98 students from our dataset. We confirmed the results of prior work demonstrating that certain acoustic features related to frequency, temporal, spectral, and energy characteristics of speech are consistently influenced by engagement levels [44]. However, we discovered that all of the features are also impacted by the interaction between clinical diagnosis and engagement level. This suggests a critical need to develop more robust measures for measuring reading engagement that can account for the unique characteristics associated with different neurodevelopmental conditions. In future work, we hope to collect more refined turn-level engagement annotations that can be used to develop acoustic feature-driven models of reading engagement based on these findings. Furthermore, by integrating these measures of reading engagement into digital literacy systems we can create personalized adaptive learning interventions to increase individual students' reading comprehension gains.

7. ACKNOWLEDGMENTS

The research reported here was supported by the Institute of Education Sciences, U.S. Department of Education, through Grant R305C240040. The opinions expressed are those of the authors and do not represent views of the Institute or the U.S. Department of Education. This work was made possible by our collaborators at Digital Promise, the Amira Learning team, the Children's Hospital of Philadelphia, and MDRC. The authors would also like to express our gratitude to the families who participated in our study and contributed to this line of research.

APPENDIX

A. PER-FEATURE GEE RESULTS

Table 7 includes all acoustic features organized by high level category as well as the results of fitting the GEE model for that feature.

ABSTRACT

We examined dynamic relationships between eye gaze, brain activity, and text characteristics during reading comprehension, a ubiquitous educational activity. We applied multilevel vector autoregression (mlVAR) to naturalistic reading data to model across-fixation (temporal) and within-fixation (contemporaneous) relationships among eye movements, EEG, and lexical features of the word being attended. We examined different approaches to encoding the multimodal time series data and how prior knowledge, reading time, mind wandering, and comprehension outcomes were related to network dynamics. Our data were from 116 participants who engaged in a complex learning task involving five long, connected texts on scientific research methods. Across model configurations, lexical features consistently predicted fixation duration, highlighting text-driven control of reading behavior, whereas EEG-gaze interactions emerged under certain model configurations. Measures of cognitive states, mainly comprehension and reading time, predicted within-fixation network connectivity. These findings demonstrate that temporally sensitive multimodal models provide a useful framework for characterizing moment-to-moment reading dynamics.

Keywords

Multimodal modeling, eye tracking, EEG, reading comprehension, temporal modeling

1. INTRODUCTION

Reading comprehension remains a key skill in education and everyday life: whether learning from a textbook in class or reading an article at home for leisure. Decades of research have shown that comprehension emerges from dynamic interactions between text characteristics, individual differences in the reader, and the reading context [72, 42, 43]. Eye-tracking has been a key modality used for understanding encoding and processing of words, sentences, and text [27, 27, 56, 12], and even for predicting comprehension outcomes and attentional states during reading [12, 24, 5, 30]. This is due to its tight link to moment-by-moment cognitive processing, a phenomenon deemed the *Eye-Mind Link*. For example, fixations (when gaze is maintained in a single spot) and saccades (quick movements between fixations) are sensitive to textual features such as word frequency and complexity [59, 55, 61]. Consequently, a weakening of this gaze-text link can be used to predict internal mental states associated with disrupted comprehension such as mind wandering [5, 30, 62]. The eye-mind link has been applied in real-time interventions to prompt readers to re-read text if they mind wander [49], or adapt texts when comprehension difficulty is detected [67]. Yet, relying on a single modality (gaze) limits these models' ability to explain and predict the complex, temporally unfolding cognitive processes that occur during reading comprehension.

Neural measures offer a more direct window into the brain (arguably the locus of the "mind") and have been used to investigate the cognitive processes that support reading comprehension. Electroencephalography (EEG) and functional magnetic resonance imaging (fMRI) provide rich information about encoding, semantic processing, and integration during reading and language processing [20, 6, 31]. Importantly, EEG measures the brain's electrical response at the millisecond scale enabling capture of fast moving brain dynamics. Here, EEG studies have focused on capturing neural dynamics on a single word using Rapid Serial Visual Presentation (RSVP) paradigm, where words are sequentially presented one at a time. Given the lack of ecological validity of this approach, some studies have used fixation-related potentials (FRPs), where EEG activity is time-locked to fixations during more naturalistic reading [19].

However, FRP studies also generally rely on highly-controlled text stimuli, including artificially constructed sentences, often restricting analysis to a subset of experimentally manipulated target words that should elicit predicted lexical

effects [20, 66, 34]. This includes removing certain short function words from analysis even though they make up a decent proportion of viewed words [10, 34], but have limited lexical information (very high frequency and low surprisal). Within these contexts, characteristic components of the FRP have been associated with linguistic variables such as surprisal (lack of predictability) and word frequency [79, 66]. However, such designs prioritize experimental control at the expense of ecological validity. They obscure how neural activity dynamically couples with eye movements to support the broader cognitive aspects of reading, such as how comprehension is constructed while reading a long connected text, and how it is affected by lapses in attention. FRP studies also tend to quantify fixations in isolation, largely ignoring the temporal dynamics across multiple fixations.

The present study focuses on modeling the temporal dynamic coupling between eye movements, neural activity (EEG), and text characteristics during natural reading of long, connected texts. We extract multivariate timeseries consisting of fixation-related EEG responses in parallel with fixation durations and linguistic features of fixated words. To capture how these features jointly evolve over time, we use multi-level vector autoregression (mlVAR) to model temporal (across fixation) and contemporaneous (within-fixation) dependencies of these timeseries across readers. This is one of the first attempts (to our knowledge) to simultaneously investigate temporal dependencies between eye, brain, and the text during relatively naturalistic reading settings.

2. BACKGROUND AND RELATED WORK

2.1 Reading Comprehension

Reading comprehension involves interacting levels of processing that unfold over time: perceptual intake and encoding of a word [36], accessing a word's literal meaning [52], constructing a representation of the text and updating it with prior knowledge from memory [40], eventually leading to a rich mental representation of what was read [42, 43]. Reading is thus a highly interactive process where readers must continually retain relevant information, reactivate earlier representations, and suppress information that becomes temporally irrelevant [80], all while continuing perceptual uptake and encoding of words as they proceed through the text.

A widely-used framework for reading comprehension distinguishes among three levels of mental representation: the surface code, textbase, and situation model [76]. The surface code reflects a literal encoding of the words and syntax of the text. The textbase captures the meaning of sentences independent of their specific wording. Finally, the situation model integrates meaning across the entire text, combining what was read with the reader's prior knowledge [35]. Cognitive theories such as Kintsch's Construction-Integration model [41, 43] explain how higher-level inferences emerge from these initial, more literal meanings of the text. This means disruptions in constructing the surface code or textbase can have downstream effects on developing the situation model [68]. For instance, if a reader mind wanders while reading a sentence containing key information, this hinders their ability to later form inferences pertaining to that information [69]. Taken together, this highlights reading comprehension as a temporally evolving process in which moment-to-moment encoding accumulates to support the construction of a coherent mental model.

2.2 Eye Movements during Reading

Linguistic processing must be tightly coordinated with the visual system to coordinate perceptual uptake [39]. As such, eye movements index and track the cognitive processes underlying reading comprehension as they unfold. Decades of research on gaze control during reading support a strong coupling between eye movements and textual features [55, 58, 27, 61]. For example, fixations occur when information is encoded, and are shorter on more frequent words [59, 58] and longer on less predictable or surprising words [55]. This relationship can even be temporally complex, as illustrated by the "spillover" effect when fixations are longer following difficult words [55, 61]. Saccades are the quick movements between fixations, and regressions are saccades to previous sections of the text and occur approximately 10%-25% of the time [57]. More difficult texts elicit more and longer fixations, as well as more regressions [14] reflecting a breakdown in encoding or integration processes [63].

This coupling between eye movements and online mental processing is deemed the Eye-Mind Link [54, 60]. Beyond indexing lower-level lexical processing, eye movements have been leveraged to predict higher-level comprehension and integration processes, such as detecting knowledge incongruence in text via characteristic regressive patterns [77]. Skim reading, typically associated with decreased comprehension [57], is characterized by fewer and shorter fixations and fewer regressions [50]. In contrast, mind wandering ("zoning out"), an attentional state also robustly linked with impaired comprehension, has a less consistent gaze signature. Mind wandering been associated with fewer fixations and regressions (similar to skim reading) and longer fixations (similiar to reading difficult texts) in some studies [4, 30, 62], but an increase in fixation count in others [75]. Other studies have explored mind wandering in regards to coupling, finding a decreased sensitivity to linguistic and lexical changes in the text[2, 11].

Given these relationships, machine learning using eye movements have been able to predict shallow [24, 73, 15, 46] and deep comprehension of texts [12], as well as mind wandering [5, 30, 62] during learning contexts. However, to address the inherent ambiguity of information in individual fixations, these models aggregate gaze features across predefined windows or entire pages of text, losing fine-grained dynamic temporal structure, which is the present focus.

2.3 EEG Correlates of Linguistic Processing

Investigating neural activity offers the potential to go beyond coarser grained eye-gaze analyses towards differentiating processing within and across fixations, enabling more precise characterization of reading dynamics. Controlled experiments using EEG have identified neural correlates of language comprehension. Event-related potentials (ERPs) measured on the scalp reflect neurons activating in synchrony [45] resulting in consistent voltage fluctuations comprising positive and negative peaks unfolding over several hundred milliseconds [45]. Linguistic ERPs are traditionally measured in tightly controlled experiments where words are presented in isolation for a brief fixed interval using RSVP

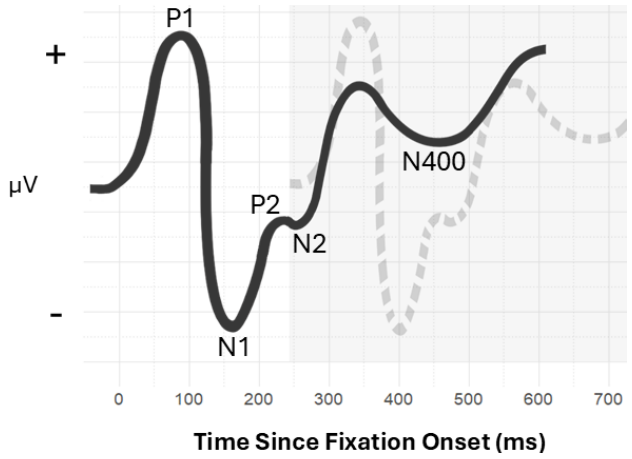

Figure 1: Characteristic FRP after the onset of a fixation with classic positive (P) and negative (N) wave components. P1 and P2 are positive peaks 100 and 200 ms after fixation onset, respectively. N1, N2, and N400 are negative wave components typically occurring in the range of 100, 200, and 400 ms after fixation onset. Grey box indicates the onset of another fixation, showing how FRPs can overlap across fixations.

[23, 20]. Whereas this approach allows for the precise delineation of the neural response to single words [21], it does not reflect naturalistic reading settings.

A fixation-related potential (FRP), on the other hand, is an ERP that is time-locked to the onset of a fixation during natural reading and allows for a richer measure of perceptual and cognitive processing that occurs during processing of a word in context [19, 20]. FRPs require more in-depth processing to remove overlapping neural responses to successive words [16, 71] and have been used during natural reading to investigate the relationship between EEG and eye movement measures [33, 23].

Early ERP components during reading are primarily associated with visual processing and encoding, and are sensitive to low-level lexical features. For instance the P1 and N1 components which occur 80-120 ms post-fixation show smaller responses for more frequent words [66]. The P2 (150-300 ms post-fixation) has been linked to early orthographic and phonological processing as well as lexical access, with amplitudes modulated by word frequency [20]. Later components, such as the well-studied N400 (300-500 ms post-fixation), reflect higher-level semantic processing and integration [79] and are sensitive to semantic predictability and contextual fit [44]. These components can overlap across successive fixations, demonstrating that visual, lexical, and semantic processes are dynamically coordinated as reading and comprehension unfold [19, 20].

The ability of FRPs to capture neural processing within a single fixation is particularly valuable in distinguishing complex cognitive states even when fixation durations are similar. In particular, longer fixation durations can arise for different reasons– either because the reader is disengaged from the text [62], or because they are allocating resources towards processing a difficult word [55, 26]. Eye movements alone cannot distinguish these cases. In contrast, EEG provides a direct window into the neural processes unfolding during a fixation, allowing covert states to be differentiated at a finer temporal scale. For example, Broadway et al. [9] showed that mind wandering during reading is associated with attenuated early visual ERP components such as P1, consistent with perceptual decoupling from external input [64]. The strength of these early neural responses predicted subsequent reading comprehension, linking momentary engagement to later comprehension outcomes. Boudewyn et al. further demonstrated that during story listening, mind wandering reduced the sensitivity of the N400 to contextual linguistic variables such as word position and surprisal [7]. More recently, Southwell et al. [74], replicated this finding involving natural reading. Using multivariate linear modeling applied to concurrent EEG and eye movement recordings, they found that mind wandering led to a decreased modulation of the N400 by surprisal, such that the amplitude of the N400 was larger (more negative voltage) during mind wandering. This further suggests a greater sensitivity to word meaning when readers are attending to the text. Together, these findings highlight the value of incorporating EEG into temporal models of reading, as neural activity captures fixation-by-fixation fluctuations in attentional and linguistic processing that are not observable from eye movements alone.

3. NOVELTY AND CONTRIBUTIONS

Reading is a temporally evolving process in which eye movements, neural activity, and textual properties continuously interact. However, most prior multimodal reading research involving the eye, brain, and text has focused on individual within-fixation associations examined under controlled experimental conditions rather than the fixation time series as a whole.

Accordingly, the goal of the current study is to provide an exploratory analysis of temporal reading dynamics across modalities and to examine how these dynamics are related to cognitive processes underlying reading. To do so, we implemented multilevel vector autoregression [29, 28], a relatively new modeling approach that enables joint estimation of across-fixation (temporal) and within-fixation (contemporaneous) relationships among eye movements, EEG activity, and lexical properties. mlVAR explicitly separates lagged dependencies across successive fixations from instantaneous coupling within a fixation, allowing these two sources of structure to be estimated simultaneously.

At the fixation level, mlVAR is implemented as a system of linear mixed-effects models in which features from the previous fixation are used to predict features at the current fixation, allowing for group-level network patterns to be estimated while capturing participant-specific deviations. By modeling multiple modalities in a unified temporal framework, mlVAR provides an exploratory lens on how gaze behavior, neural activity, and lexical properties co-vary over time. This approach enables our first research question **(RQ1): What are the within- and across-fixation relationships between EEG, gaze behavior, and text during naturalistic reading?**

The second aim of the study is to explore how cognitive processes modulate these dynamic relationships. Specifically, we ask **(RQ2): How do mind wandering, comprehension, prior knowledge, and reading time relate to variation in reading dynamics?** These factors are treated as sources of variability in the strength of dependencies among eye movements, neural activity, and text. While some of these cognitive variables have been explored at the level of single fixations, they have not been jointly modeled across modalities or across successive fixations.

Finally, because most FRP approaches do not model fixation sequences over time, they do not require preserving temporal continuity. Accordingly, it is common for these approaches to exclude stop words (short words that include articles, prepositions, conjunctions, and pronouns, e.g., "a", "the", "in", "or"), and restrict analyses to content words (e.g., nouns, words). However, stop words and their associated fixations are an integral part of the reading process and how readers move through, pause on, or transition across these words may carry meaningful information about cognitive state. For example, prolonged fixations on stop words may reflect mind wandering. We therefore introduce **(RQ3): How do different strategies for representing stop words into the fixation time series shape the temporal effects and cognitive influences observed in the model**.

To address this, we compare three modeling strategies (see Figure 4). Given that the definition of the $t-1$ fixation is the key modeling detail in mlVAR, we tried three modeling strategies that differed in how stop words were incorporated into the definition of the $t-1$ fixation. In Model 1 we used only transitions from content words to content words, making no assumptions about stop words and excluding transitions that were originally to or from stop words. This keeps the focus to content words, most clearly mirroring traditional FRP analysis. Model 2 assumes stop words are minimally processed and barely attended to, effectively skipping them by removing stop word fixations and modeling a sequence of fixations represented as between fixation content words only. In other other words, the $t-1$ fixation is defined as the previous content word attended to. Lastly, Model 3 retained stop words in the sequence by imputing them with the lowest surprisal and highest frequency values, allowing the fixation sequence to include both content words and stop words. These modeling strategies will unveil how important assumptions shape which aspects of coupling are emphasized. See Figure 2 for a visualization of each modeling strategy.

The novelty of this work lies in applying mlVAR to multimodal fixation-level, real-world reading to explore patterns that can inform future theory-driven and application-focused modeling efforts. To our knowledge, no study has investigated the temporal dynamics of eye gaze, EEG, and text characteristics during naturalistic reading of long expository educational texts. As a result, our findings can be useful in educational contexts.

4. DATASET

This study was part of a larger study and only aspects germane to the present research are discussed here.

4.1 Participants

A total of 116 participants (mean age = 22 +/- 5.7 (SD), 70% female, 1% identifying as another gender) were students from a large public university in the western United States. Participants were compensated $20 per hour via Amazon gift cards. All procedures were approved by the university's Institutional Review Board, and written informed consent was obtained from all participants prior to participation.

4.2 Data Acquisition

4.2.1 Eye Tracking

High-resolution, binocular gaze was tracked using the desktop-mounted SR Research EyeLink 1000+ with a sampling rate of 1000 Hz. Stimuli were displayed on a 23.8", 1920x1080 pixel display and viewed at a distance of 90 cm. Participants stabilized their head using a chin rest.

4.2.2 EEG

EEG was recorded at 1000 Hz using a LiveAmp wireless amplifier with 8 electrodes on an ActiCAP (Brain Products GmbH, Munich, Germany cite). A custom layout based on the 10-5 system was designed to optimize scalp coverage while also working around other sensors present on the cap. The montage included two standard mid-line locations (CPz and FCz), 3 pairs of symmetrically-located channels at frontal (AFF5h and AFF6h), centro-parietal (CCP5h and CCP6h), and parieto-occipital (PPO9h and PPO10h) locations. Reference was at Cz and Ground adjacent to FPz.

4.3 Reading Task & Measures

4.3.1 Texts and Reading Procedure

Participants read five expository texts on the computer monitor, totaling in 5306 words over 50 pages (mean 106 words per page). Each text consisted of ten pages (screens) of text and participants could advance through the pages at their own pace, but could not return to pages already read. Texts were presented in a random order, and each focused on a topic of behavioral research methods: Hypothesis, Bias, Causal Claims, Validity, and Variables. The texts had a mean Flesch-Kincaid grade level of 13.2, indicating a slightly advance reading level suitable for college students [32]. Participants spent an average time of 27.6 (8.3 SD) minutes reading all texts. On average, 57.3% $\pm$ 3.4% of words on a page were content words.

4.3.2 Reading Time

Page-level reading times were calculated from the beginning of the button press that initiates the page, to the next button press that leaves the page. Mean reading time per person was calculated by average page-level reading times across the entire text. Pages with short reading times (<10 seconds) were excluded, as they likely reflect insufficient engagement with the text rather than meaningful reading. Participants spent an average of 36 seconds (16 SD) per page.

4.3.3 Mind Wandering Probes

We used a probe-caught method previously validated to track mind wandering [65, 78]. With this method, participants indicate if they were mind wandering on the previous page via thought-probes presented throughout the study.

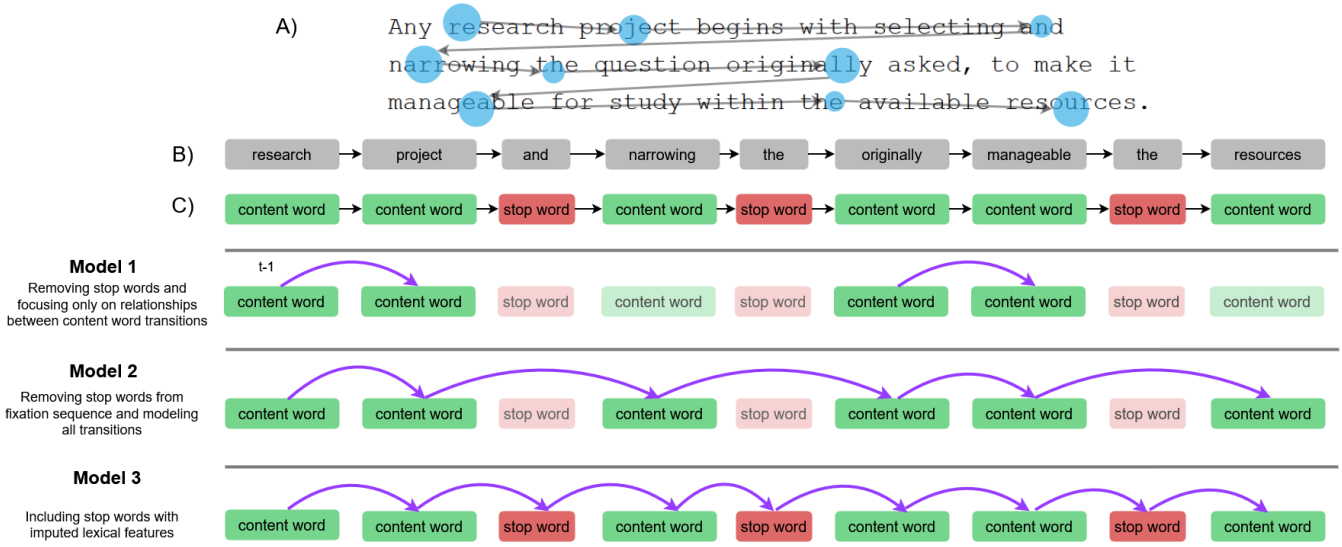

Figure 2: Illustration of a fixation sequence that consists of content words and stop words. A) Demonstrates an example sentence with eye-movements overlaid on individual words. B) The corresponding sequence of words in the order they were attended to. C) Words categorized at content words or stop words. The purple lines indicate the t-1 fixation that mlVAR models. Model 1 ignores stop words and as such, transitions from stop words, estimating temporal dependencies only between successive content words. Model 2 removes stop words from the fixation sequence, creating direct transitions between adjacent content words. Model 3 retains stop words and includes them in the temporal model with lexical features imputed.

Before beginning to read, participants are given the definition of mind wandering and instructions on how to respond to the probe. Mind wandering, or "zoning out", was defined as "not thinking about what you are actually reading, but thinking about something else altogether". Participants are asked to be as honest as possible, and informed that reporting mind wandering does not affect their progress in the study. Probes occurred twice per text on pseudo random pages, for a total of ten probes throughout the reading (see 4.3.1). When participants advanced to the next page, they would first be prompted with a yes or no question asking if they were mind wandering on the previous page. The average mind wandering rate was 47% (24% SD).

4.3.4 Comprehension Questions

Reading comprehension was measured via three different types of assessments that target different levels of comprehension. Rote questions were four-item multiple choice targeting factual knowledge explicitly presented in the text. Inference questions consisted of a statement reflecting either a true or false inference that can be made by extracting implicit information from a specific single sentence on the page. Finally, integration questions were four-item multiple-choice questions assessing deeper, integrative knowledge across multiple pages.

These comprehension questions were administered at three different time points, but not all questions were administered at each time point. Questions were administered 1) during texts, meaning the questions appeared after reading the corresponding page; 2) after an individual text was read; 3) after all five texts were administered. Rote and inference questions were administered at all time points, while integration questions were only administered during texts and after all texts were completed (time points 1 and 2). Questions always appeared in the order of Rote, Inference, Integration to reflect the increasing levels of processing, and were preceded by the mind wandering probes (see Section 4.3.3). Additionally, pages that triggered comprehension questions were selected pseudorandomly with basic constraints, such that no questions never appeared on the first page or adjacent pages of the text. The specific questions administered to each participant were selected pseudorandomly from a main question pool without repetition. Mean comprehension across all questions was 68% (10% SD).

4.3.5 Prior Knowledge Assessment

Participants completed the prior knowledge assessment prior to beginning the reading task. The participants had to match six definitions relating to scientific methods with their concept names. All definitions and names were randomly ordered (Confound, Placebo, Dependent Variable, External Validity, Control Group, and A priori). Correct answers were summed. Mean prior knowledge score were 68% (17% SD).

5. DATA PROCESSING AND MODELING

5.1 Time series measures

5.1.1 Lexical Variables

Two lexical features were extracted per-word: surprisal and the log of word frequency. Surprisal for each word was computed as the negative log probability assigned to that word after inputting its page into a pre-trained GPT-2 small language model, as this model has been shown to align closest with human reading times [51]. English word frequency was calculated using the nltk package then log-transformed. Lexical variables were only defined for content words in this

Table 1: Summary of gaze, lexical, and EEG variables included in the analysis.

Variable	Description
Word Frequency	Log-transformed word frequency, indexing how commonly a word occurs in natural language.
Surprisal	Lexical surprisal computed as the negative log probability of a word given its preceding context, reflecting contextual predictability.
Fixation Duration	Duration (in milliseconds) of a single eye fixation on a word during reading.
Mean P1	Mean EEG amplitude in the P1 time window (70-120 ms) extracted from posterior scalp regions for each fixation.
Mean P2	Mean EEG amplitude in the P2 time window (140-280 ms) extracted from central scalp regions for each fixation.
Mean N400	Mean EEG amplitude in the N400 time window (300–500 ms) extracted from central scalp regions for each fixation.

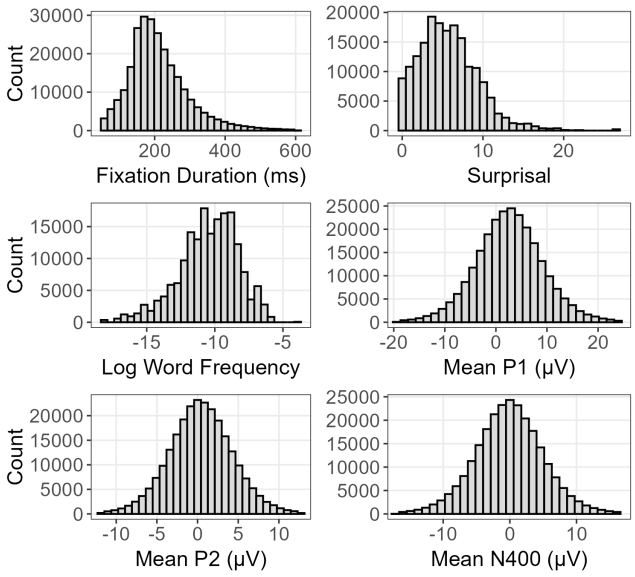

Figure 3: Histograms of gaze, lexical, and EEG variables included in the analysis. Lexical variables are for content words only. EEG variables are displayed ± 3 standard deviations. All other variables show complete range.

dataset; surprisal and word frequency values for stop words were not computed. In Model 1 lexical features for stop words were kept as missing. In Model 2, they were removed. Finally, in Model 3, lexical features were imputed to be the minimum surprisal and maximum frequency. Surprisal for content words in the text ranged between 0 and 26.5, with a mean and SD of 5.3 ± 3.5. Log word frequency ranged from -17.98 to -2.92, with a mean of -10 and SD of 2.1. Figure 3 shows distributions of lexical variables.

5.1.2 Gaze Preprocessing

Fixations, blinks, and saccades were identified from the raw time series with EyeLink's event-detection algorithm (velocity threshold of 30 degs/sec and acceleration threshold of 9500 deg/s^2). The right eye was used in the analysis if available, otherwise the left eye was used. The first and final fixations on each page were removed, as they are likely to be confounded with visual evoked potentials and motor artifacts (1.5% of fixations). Fixations with extreme durations (>600 or <50 ms) were also removed (5.1%), and pages with fewer than ten fixations were excluded (0.07%). The analysis focuses on relationship between lexical features, EEG, and gaze duration, so fixations not on words (no lexical information) or on punctuation were removed (5.12% of fixations). A total of 252795 fixations were included in the analyses, 28.37% of which were on stop words.

5.1.3 EEG Processing and FRP Extraction

EEG was time-locked to stimuli via trigger pulses generated at page transitions and other task-related events. Then EEG and eye-tracker data was aligned using a custom timestamp interpolation algorithm in Matlab R2021a [38] that accounted for timing drift between recording systems and accommodated missing triggers. For EEG preprocessing, line noise at 60 Hz was removed using the Zapline algorithm [17], and slow drifts were removed via robust detrending [18]. Bad channels were identified with the PREP pipeline [3] and interpolated from neighboring electrodes. All data was subsequently referenced to the average over all electrodes.

FRPs were estimated using a linear deconvolution approach implemented as a regression model to correct for potentially overlapping neural effects time-locked to word fixations [16, 22, 70]. For each participant and EEG channel, a linear model was fit to the continuous EEG time series. The model included categorical regressors marking the onsets of fixation events (separately for fixations on and off words), and additional regressors for blink and button-press events. This minimal model was chosen to estimate fixation-locked FRPs without imposing assumptions about cognitive or textual effects on the EEG.

Mean component amplitudes were extracted within predefined time windows and scalp regions of interest. This includes three canonical ERP components: P1 (70-120 ms) , measured over posterior visual regions; P2 (140-280 ms) measured over central and fronto-central regions; and N400 (300-500 ms), measured over central regions. These components and regions are selected based on prior literature and ensure separability given the limited spatial resolution of the EEG montage. For each fixation, component features were computed as the mean voltage within the corresponding time window and scalp region.

5.2 Multilevel Vector Autoregression

Multilevel vector autoregression (mlVAR) is a network analysis method that combines vector autoregression with linear mixed-effects modeling [8, 29]. Vector autoregression is the process of predicting a vector of variables at time t (index in sequence) using the same vector at time $t - n$, where n is lag. Combined with linear mixed effects models, this allows modeling of temporal dependencies among multiple

variables while accounting for the nested structure of the data (fixations within pages, and pages within individuals). We used the R package "mlVAR" (version 0.5.2) for all analysis [28].

5.2.1 Temporal Networks

First, mlVAR estimates temporal networks by sequentially predicting the vector of word-level EEG, gaze, and lexical variables for participant i at time t (denoted $Y_{i,t}$) from the same set of vectors at the previous time point $t-1$ using a mixed-effects formulation:

$$Y_{i,t} = Y_{i,t-1}\mathbf{B} \ + Y_{i,t-1}\mathbf{U}_i \ + \varepsilon_{i,t} \quad (1)$$

B is the fixed effects matrix that contains the average estimates of population-level lagged effects between all variables. U_i is the random-effects matrix that captures participant-specific deviations from these temporal relationship. $\epsilon_{i,t}$ is a matrix of residual error term. Each row of B corresponds to a separate regression model predicting one variable at time t from all variables at time $t-1$.

The resulting fixed-effects coefficients then form the directed temporal networks. In these networks, a significant edge between two variables indicates that the "earlier" variable $(t-1)$ significantly predicts the "later" one (t), after controlling for all other variables. Statistical significance was determine using a threshold of $p < 0.05$, consistent with prior work [25, 37].

5.2.2 Contemporaneous Networks

In addition to temporal effects, mlVAR estimates contemporaneous networks. These capture associations between variables occurring at the same time point after accounting for lagged temporal dependencies. Contemporaneous networks are computed from the residual covariance structure of the temporal models. This reflects relationships between variables that co-occur within the same fixation but are not explained by prior states of the system (temporal effects or other variables).

Let ε_{it} denote the vector of residuals obtained from the temporal model for participant i at time t. Contemporaneous associations are modeled by predicting each residual from the remaining residuals at the same time point using a mixed effects formulation:

$$\varepsilon_{it} = \varepsilon^*_{it}\mathbf{H} \ + \varepsilon^*_{it}\mathbf{G}_i \ + e_{it} \quad (2)$$

where ε^*_{it} denotes the vector of residual excluding the outcome variable currently being predicted. The fixed-effects matrix H contains population-level contemporaneous associations between variables, while G_i captures participant-specific deviations from these associations. The term e_{it} represents residual error.

Each row of H corresponds to a regression predicting one variable's residual at fixation t from the residuals of all other variables at the same time point. The resulting fixed-effects coefficients from an undirected contemporaneous network, in which an edge between two variables reflects their partial association within the same fixation, after controlling for all lagged temporal effects and the variance shared with all other modeled variables. Conceptually, whereas temporal edges represent predictive, directional associations across successive fixations, contemporaneous edges capture instantaneous co-fluctuations between gaze, EEG, and lexical variables that arise within a single fixation and are not attributable to prior dynamics.

5.2.3 Selection of Focal Network Edges

While all edges between all variables were modeled in mlVAR, we focus on a subset of cognitively-relevant edges in both networks which address our research questions. Specifically, in the temporal network, we examine directed edges from text $\rightarrow$ EEG and text $\rightarrow$ fixation duration (gaze), which capture how lexical properties (surprisal and word frequency) are related to fixation duration and FRPs on the subsequent word. We additionally consider gaze $\rightarrow$ EEG, reflecting how the amount of visual attention allocated to a word modulates subsequent neural processing, as well as EEG $\rightarrow$ gaze edges, which capture how neural indices of processing are associated with attentional allocation on the following word.

In the contemporaneous network, we included the same edges but without directional components: text $\leftrightarrow$ EEG, text $\leftrightarrow$ gaze, and gaze $\leftrightarrow$ EEG. Figure 4F shows the contemporaneous networks with these focal edges visualized. These fall into only three categories because contemporaneous edges are undirected and reflect symmetric associations between modalities that co-occur within a fixation.

Edges directed into lexical feature were excluded, as these features are properties of the text rather than of the reader and therefore do not reflect cognitive dynamics. Self-loops (edges which a variable predicts itself at the next time step) were also excluded, as they primarily reflect temporal autocorrelation rather than theoretically informative cross-modal associations. EEG self-loops in particular are difficult to interpret, as correlations across successive FRPs may arise from shared baseline activity, slow drifts, or differences in overall signal amplitude rather than meaningful cognitive processing across fixations.

By restricting analysis to focal cross-modal edges, we emphasize relationships that reflect dynamic interactions between text properties, eye movements, and neural responses during reading. Figure 4D illustrates the fourteen direct focal edges considered in the temporal network.

6. RESULTS

6.1 Temporal and Contemporaneous Effects

We first address RQ1 by examining network structure across models. Table 2 shows the significant edges and their weights. Overall, core lexical-to-gaze effects emerged within-fixations, and across fixations. These effects were consistent in direction across modeling approaches. EEG-related effects, in contrast, appeared only under certain modeling conditions.

Across both temporal and contemporaneous networks, surprisal to fixation duration had a positive effect and word frequency to fixation duration had a negative effect. These relationships are robust and were observed across all three

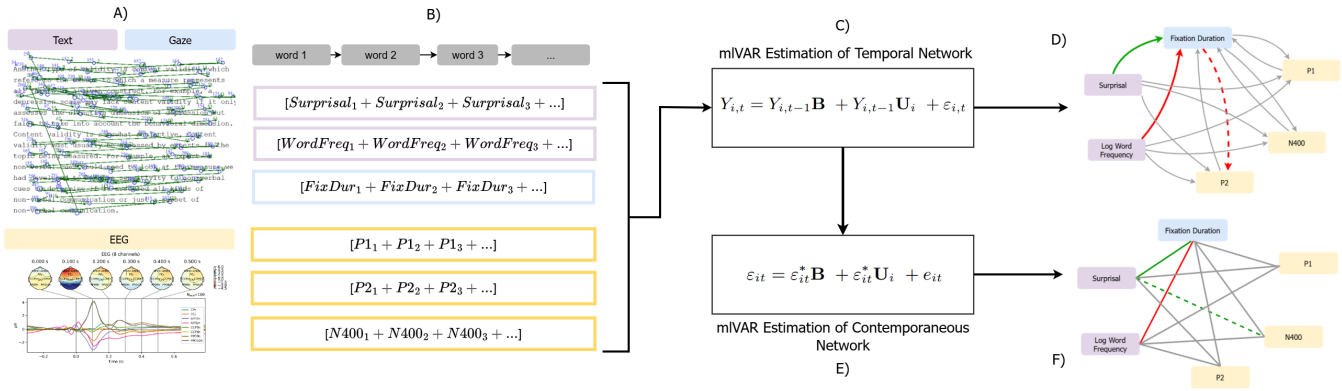

Figure 4: Study pipeline from data to final temporal and contemporaneous networks. A) Fixations and corresponding word are extracted. Fixation-related potentials (FRPs) are extracted across EEG electrodes. B) Time series is index in the order words are looked at. For each fixation, the duration is extracted along with the surprisal and word frequency of the attended word. Mean P1, P2, and N400 from relevant channels and time windows are extracted for each FRP. C) All vectors are then assessed with the mlVAR algorithm to extract temporal dependencies, which are visualized in D) where significant positive relations are in green and negative are in red. Solid lines are significant across all three models while dotted are not. E) Residuals from the temporal network are then used to estimate the contemporaneous, within-fixation dependencies using mlVAR. F) Visualization of the contemporaneous network, following the same labeling as the temporal.

Table 2: Significant temporal and contemporaneous edges across models. Temporal edges are represented as β. Contemporaneous edges are represented as ρ. $p < 0.05$ for all reported values. M1, M2, and M3 indicate Models 1, 2, and 3 respectively.

Temporal edges			
Edge	**M1**	**M2**	**M3**
Surprisal → Fixation Duration	0.012	0.010	0.011
Word Freq → Fixation Duration	-0.020	-0.012	-0.012
P2 → Fixation Duration			-0.006
Contemporaneous edges			
Edge	**M1**	**M2**	**M3**
Surprisal ↔ Fixation Duration	0.019	0.021	0.016
Word Freq ↔ Fixation Duration	-0.015	-0.019	-0.021
Surprisal ↔ N400		0.005	0.004

models. The direction of these effects align with previous research examining within-fixation patterns. Specifically, longer fixations are typically observed for words requiring deeper processing: either because they are low frequency words or are surprising, unpredictable words given the sentence context [53, 55]. The fact that these relationships were observed in the temporal models suggests a spillover effect in which word properties for fixation t influence gaze patterns for fixation $t+1$.

Two additional edges involving EEG features emerged in particular networks and model configurations. In particular, the temporal network in had a negative edge between mean P2 and subsequent fixation duration: as mean voltage within the P2 window (140-280 ms after fixation onset) became more positive, fixation duration of the next word decreases. Increase in the P2 magnitude has been previously linked to an increase in early word-level processing within-fixations [1, 20], but has been less explored temporally. Interestingly, this association is only present in Model 3, which contains stop words that usually have shorter fixation durations. Taken together, this effect may reflect either reduced attention to the upcoming word following larger P2 response or a greater likelihood that the subsequent fixation lands on a word (like a stop word) that typically requires less processing.

Surprisal also showed a positive within-fixation association with the mean N400 in the contemporaneous networks for Models 2 and 3. That is, as surprisal increased, the mean value in the N400 window (300-500 ms) became more positive (less pronounced negative amplitude). This conflicts with previous research showing higher surprisal linked to an larger negative peak in the N400 [44]. However we use a mean voltage value within the analysis window. It is possible the mean value captures too much surrounding activity in the FRP, pulling the value more positive when shifts in the timing of the N400 peak occur. Additionally, imputing stop words affects the surprisal distribution in ways not traditionally modeled. Because stop words have very low surprisal, assigning them imputed values changes which surprisal values are most common in the data, so the surprisal-N400 relationship is estimated from a different mix of words than typical ERP studies.

Although individual edge magnitudes are small, this is expected in a multivariate time series of fixation-level data where effects reflect incremental, conditional associations after accounting for strong autoregressive and cross-modal dependencies. Small estimates at the fixation level can accumulate across the thousands of fixations per participant. Importantly, these effects were highly stable as evidenced by the following permutation tests.

6.1.1 Permutation Testing

To assess the robustness of the estimated network structures, we conducted a participant-level permutation subsampling analysis. Twenty five random subsamples of fifty

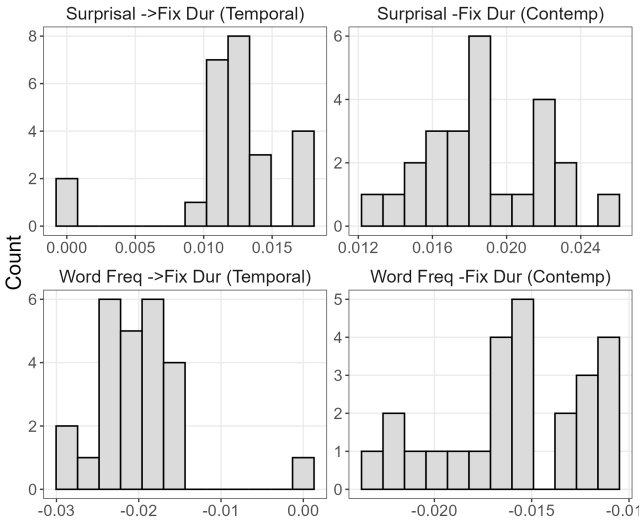

Figure 5: Histograms of edge weights from the 25 permutations for the two significant edges in the temporal and contemporaneous networks for Model 1

participants each were drawn without replacement, and the mlVAR model was fit for each. Temporal and contemporaneous networks were extracted from each fitted model, and edge weights were aggregated across permutations to form empirical distributions for each network connection. We conducted this analysis using Model 1 as an illustration. Edges identified as significant in Model 1 were verified with a 95% confidence interval of their permutation distribution excluding zero. This procedure evaluates whether observed network dependencies reflect stable population-level relationships rather than effects driven by a small subset of participants, providing a robustness of the mlVAR results.

Permutation testing on Model 1 consistently showed the same significant edges. In the temporal network, the 95% confidence interval for the significant edges were [0.010, 0.014] for Surprisal → Fixation Duration and [-0.022, -0.018] for Word Frequency → Fixation Duration. In the contemporaneous network, the corresponding intervals were [0.018, 0.020] Surprisal ↔ Fixation Duration for and [-0.017, -0.015] for Word Freq ↔ Fixation Duration. These confidence intervals that do not overlap with 0 (null effect) indicate that the observed associations are reliable and robust despite their small magnitudes.

6.2 Cognitive Variables as Predictors of Network Connectivity

To address RQ2 we examined cognitive variables as predictors of connectivity in the temporal and contemporaneous networks for each model. Specifically, we leveraged the multilevel structure of the mlVAR model to extract participant-specific edge estimates. Because temporal edges are estimated using hierarchical linear mixed effects models, we can extract participant-level deviations from the group-level network. We extracted the fourteen participant-level temporal edges for each individual, for each relevant directed connection in the network as well as the 11 focal contemporaneous

Table 3: Contemporaneous models cognitive effects on total connectivity (Mean per-person and standardized). Regression coefficients (β) and p-values are reported. Significant effects ($p < .05$) in bold.

	Model 1		Model 2		Model 3	
Predictor	β	p	β	p	β	p
Reading time	-.11	.25	.05	.59	**-.27**	**.00**
Comprehension	**.24**	**.03**	**.25**	**.02**	.08	.46
Prior knowledge	-.02	.81	-.03	.75	-.11	.28
Mind wandering	-.02	.82	-.02	.88	.03	.78
Observations	116		116		116	
R^2 / Adj. R^2	0.07 / 0.04		0.06 / 0.03		0.08 / 0.04	

edges. We then investigated how participant-level differences in comprehension outcomes, mind wandering rates, prior knowledge, and reading time predicted total connectivity in the focal edges in each network (Figure 4). We calculated total connectivity as the sum of the absolute value of each focal edge (14 edges in temporal network and 11 edges in the contemporaneous network). We used the following linear regression model:

$$\begin{aligned}\text{Connectivity} \sim \text{Mind Wandering}_{\text{mean}} + \text{Comprehension}_{\text{mean}} \\ + \text{Prior Knowledge}_{\text{mean}} + \text{Reading Time}_{\text{mean}}\end{aligned}$$

Results are shown in Table 3. There were no significant associations between the cognitive variables and total connectivity in the temporal networks. The contemporaneous networks, however, had positive effects of Comprehension in Models 1 and 2, and a negative effect of reading time in Model 3.

These results suggest that higher comprehension is associated with stronger within-fixation coupling between modalities when stop words are excluded (Models 1 and 2). One interpretation is that readers who achieve better comprehension exhibit more tightly coordinated processing across gaze, neural, and lexical signals. Greater total connectivity may reflect a more cognitively coupled state in which the modalities co-vary more strongly [48]. Importantly, this association does not imply a directional relationship between comprehension and connectivity, but instead highlights that stronger comprehension tends to co-occur with denser contemporaneous structure in the multimodal network. That absence of this pattern when stop words are retained further suggests that this coupling is more evident during fixations on content-bearing words, which entails integration of lower-level of processing into a coherent mental model of the text including making bridging inferences from previous parts of the text and also elaborative inferencing from long-term memory [47].

In contrast, when stop words are included (Model 3), longer reading times are associated with weaker contemporaneous connectivity. Reading time is a complex measure that can indicate skimming, scanning, or deep reading strategies [13], each of which is reflected in distinct gaze patterns. Increased reading time can also function as a compensatory strategy when comprehension difficulty occurs [13]. Readers

may compensate by slowing down or through regressive (i.e., re-reading) eye movements [54], which would increase reading times. Here, longer reading times were associated with weaker contemporaneous network connectivity, i.e. weaker coupling between modalities occurring within-fixation. One interpretation is an association between comprehension difficulties (longer reading time to repair difficulties) and weaker network structure.

Lastly, neither prior knowledge nor mind wandering were predictors of network connectivity. It is possible these variables show selective differences across network edges rather than changes in overall connectivity.

7. DISCUSSION

The primary aim of this work was to examine how multimodal temporal modeling can help uncover moment-to-moment eye-mind coordination between gaze, fixation-related potentials, and text characteristics during reading. Our findings illustrate how fixation-level mlVAR can serve as an exploratory tool to examine temporal and within-fixation coupling (RQ1), and examine cognitive associations on network connectivity (RQ2), and compare different approaches for representing the time series (RQ3). Although, we focused on the specific domain of reading comprehension here, our we aim for the overall modeling approach to be informative and potentially useful to related domains in educational data mining.

7.1 Main Findings

Regarding RQ1, the observed temporal and contemporaneous networks align with classic accounts of the eye-mind link that emphasize a close coupling between linguistic processing and eye-movement behavior during reading. Moment-to-moment gaze dynamics were sensitive to the lexical properties of the text, consistent with long-standing views that fixation duration reflects ongoing word-level processing. Additionally, the temporal effects across fixations extend prior static within-fixation analyses by showing that these established lexical-gaze relationships might be anticipatory or signal spillover effects. Neural associations were less stable and more sensitive to how fixation sequences were represented.

We explored RQ2 by investigating effects of participant-level cognitive variables (mind wandering, reading time, prior knowledge, comprehension) on total network connectivity. Comprehension and reading time showed effects in the contemporaneous network only: reading comprehension scores predicted connectivity whereas reading time negatively predicted it. Overall, these effects are consistent with theoretical perspectives highlighting a tight coupling between the eye, brain, and text required for successful comprehension, and that increased reading times might signal comprehension difficulties and repair strategies. Rather than treating the models as competing methods, we interpret them as complementary lenses on the same underlying reading process, each making different assumptions. Differences in cognitive effects across models reflect how these assumptions shape which aspects of multimodal coupling are emphasized, rather than indicating that one model is more correct than others. More research is needed to examine how the reported effects are sensitive to modeling choices.

Finally, to address RQ3, we compared results across three modeling strategies that differed in how function words (stop words) were treated in the determination of $t-1$ fixations for temporal modeling. Model 1 preserved only the content-to-content word transitions that were originally present in the fixation sequence, making no assumptions about stop words and excluding any transitions to or from stop words. Model 2 treated stop words as minimally processed and short in duration, effectivity skipping them by removing stop-word fixations so that all modeled transitions occurred between content words. Model 3 retained stop words in the sequence by imputing them with the lowest surprisal and highest frequency values, allowing fixation sequences to include both content and function words.

Core lexical-gaze relations were stable to different stop word treatments, while neural-gaze and lexical-neural associations were more model dependent. Given the additional P2 to fixation duration and surprisal to N400 edges in Model 3, neural coupling might be more sensitive to how stop words are handled, potentially due to prediction mechanisms that are not captured in the eye gaze sequence. Additionally, a negative effect of reading time on total contemporaneous connectivity was found only in Model 3. Because stop words are associated with minimal semantic processing and brief fixations, including them may reduce the coherence of within-fixation multimodal structure, though this needs to be examined further.

7.2 Limitations

A primary limitation of our study is the interpretation of findings given the nature of the analyses. Although we examined associations between cognitive measures and network properties, the results do not support claims about underlying mechanisms or directional relationships (e.g. whether higher comprehension stems from stronger connectivity or stronger connectivity stems from better comprehension). Addressing such questions requires analytic approaches beyond the correlational framework used here. Second, the temporal resolution of the model is constrained to the fixation-level. Cognitive processes involved in reading do not always unfold at the timescale of individual fixations, and lag-1 dependencies might fail to capture longer-range dynamics across words, sentences, or pages. Additionally, cognitive measures were aggregated at the participant-level, which may obscure moment-to-moment variability in cognitive states. Lastly, our data were collected in a specific lab setting where participants wore a neural cap, read expository texts, wore masks (due to Covid-19). Thus, it is unclear whether our findings can be generalized to more ecological reading scenarios.

7.3 Concluding Remarks

The eye-mind link is inherently dynamic, relying on moment-to-moment coordination between text, gaze, and neural activity. The results presented here suggest that temporal modeling of fixation sequences can recover well-established patterns from the reading literature while extending them to richer, multimodal, relationships and elucidating temporal effects. This approached helps assess whether relationships typically observed in isolation or within-fixations are observed in the context of full-length sequences with temporal interdependencies across fixations. While lexical properties show robust associations with subsequent fixation du-

ration, incorporating EEG alongside gaze measures offers additional information for tracking cognitive states during reading. Our findings also suggest that low-level details in how the underlying time series are encoded can have major implications on the conclusions. Lastly, while we focused on reading comprehension and a specific multimodal configuration of signals here, the overall mlVAR approach can be applied to any set of modalities collected across a range of domains, thereby providing new insights into the learning process.

ABSTRACT

Sustained effort is essential for realizing the benefits of intelligent tutoring systems (ITS), yet many learners disengage or underuse available practice time. We introduce *engagement forecasting* as a supervised prediction task based on ITS logs, targeting two outcomes central to effort and learning progress: **minutes practiced per week** and **new skills mastered per week**. Using interaction log data from 425 middle-school students over a school year, we benchmark fifteen predictors including regressions, decision trees, and neural networks. We show that these feature-based models reduce mean absolute error (MAE) by 22–33% relative to heuristic baselines, including fixed-percentile rules adapted from prior work in other behavioral domains. We find that percentile heuristics systematically overpredict, whereas feature-based models better track student practice trajectories across weeks. To support explainability, we analyze feature importance and ablations, revealing target-specific patterns: effort forecasting is driven mainly by recent activity features, while progress forecasting depends more on learner-state and content difficulty signals. Finally, in a semi-structured user interview case study with eight college tutors, we examine how tutors reasoned about system-generated predictive features when setting goals with students. We find that tutors reasoned differently about effort versus progress goals in ways that mirror our pattern analysis. Together, these results establish a reproducible benchmark for forecasting weekly effort and learning progress in ITS. By making patterns of sustained effort and progress visible at a weekly timescale, engagement forecasting offers a foundation for supporting tutor–learner goal setting and timely instructional decisions.

1. INTRODUCTION

Active learning systems that scaffold student problem solving can substantially improve learning outcomes, especially when learners engage in high volumes of practice with feedback over several months [36, 33]. Yet, persistence and effort remain bottlenecks: many students disengage after initial practice or do not utilize the class time they have at their disposal, limiting these systems' long-term impact [25, 31]. In large-scale deployments, engagement is often highly skewed—for example, only a small minority of students may reach recommended weekly usage levels [29, 24, 22]. This disparity in engagement motivates a central question: how can analytics predict and explain differences in student effort to generate actionable, learner- and teacher-facing insights that support effort regulation?

In this paper, we introduce *engagement forecasting*: a supervised prediction task that estimates a learner's next-week engagement level from prior ITS interaction traces. We focus on two engagement indicators that are both observable in ITS logs and directly relevant to effort regulation support: **minutes practiced per week** (effort) and **new skills mastered per week** (learning progress) [41]. We adopt these targets not as complete measures of motivation or learning, but as simple, observable signals that tutors and platforms already use for week-to-week planning [24], making them suitable for decision support even when imperfect.

Importantly, student engagement in ITS is constrained, but not fully fixed. Middle-school students typically engage with tutoring software within clear boundaries set by teachers and schools, such as designated class time and homework policies. Yet, students still exercise agency within these constraints: how consistently they use allotted time, whether they persist across weeks, and how they respond to prior success or difficulty. This motivates engagement forecasting at an intermediate (e.g. weekly) time scale: it can serve as actionable decision-support signals for teachers and students, helping guide agency and self-regulation as students progress through the school year [42].

A key challenge in forecasting engagement is identifying

which aspects of learner context matter. Motivational theory suggests that persistence is shaped by beliefs about competence (often discussed as self-efficacy) as well as recent success and failure experiences [40, 51]. From an analytics perspective, some of these factors are indirectly observable in ITS logs through patterns in learner interactions. For example, difficulty and learning rate—long studied in EDM through models such as the Additive Factors Model (AFM)—may influence whether continued effort translates into progress or discouragement [15]. Rather than posing a new theory of motivation, we seek empirical insights into which of these log-derived signals are most predictive of next-week engagement targets.

We compare feature-driven predictive models against strong heuristic baselines. In addition to common algorithms (e.g., mean and median), we evaluate percentile rules adapted from adjacent health behavior domains [1, 13]. These percentile heuristics often assume sustained week-over-week improvement; whether that assumption transfers to K–12 tutoring settings is an open question [25]. We further conduct feature attribution and ablation tests across four feature groups derived from ITS logs: AFM-based learner state, recent activity trends, practice gaps, and prior achievement. By evaluating these groups, we seek to identify which contextual signals are most predictive of student effort, potentially using these insights to improve future ITS adaptivity [52]. To move towards closing this loop, we conduct a semi-structured user interview to examine how tutors can use the explainable signals when setting goals with students. We ask the following research questions:

RQ1: How well can data-driven approaches improve forecasting of next-week effort and progress?
RQ2: Do percentile heuristics drawn from other contexts (e.g., health and sports) generalize to engagement forecasting in K–12 tutoring settings?
RQ3: Which features available from ITS data are most indicative of next-week effort and progress?

This paper contributes to EDM theoretically and practically. First, we introduce week-ahead engagement forecasting in ITS as a new prediction task, focusing on calendar-level effort and progress to support practical instructional decision-making, complementing prior EDM work such as affect detection, wheel-spinning, and dropout prediction. With **RQ1** and **RQ2**, we show that statistical learning is a valid approach to the task that outperforms and better tracks student trajectory compared to existing heuristics. Second, through feature analysis in **RQ3**, we provide theoretical insights into the structure of engagement, showing that effort and progress are predicted by qualitatively different features (recent activity vs. learner-centered signals). Third, we use a user interview case study to examine how these predictive signals align with tutors' reasoning about engagement and goal setting, moving towards closing the loop between engagement forecasting and improving learning benefits.

2. RELATED WORK

We review prior work in (1) modeling effort, engagement, and disengagement in ITS; (2) foundational accounts of persistence and effort regulation; and (3) prediction tasks in EDM. Across these areas, prior work motivates why effort is a distinct and consequential target, but also highlights that personalized, data-driven forecasting of week-ahead effort and progress remains underexplored.

2.1 Effort and Engagement Modeling in ITS

ITS generate fine-grained logs of student practice that enable automated feedback and data-driven analysis [3, 47]. While ITS can improve learning outcomes, their impact is often constrained by the lack of sustained student engagement over long time horizons [29, 11]. For example, large-scale deployments can exhibit substantial skew in usage, with many learners falling below recommended practice levels [24, 22]. This motivates analytics that focus not only on *knowledge progress* but also on *effort and persistence* as first-class targets.

A substantial body of ITS research has modeled engagement-related phenomena such as off-task behavior, gaming the system, and other forms of disengagement using interaction traces (e.g., response patterns, hint usage, timing signals, delayed starting), often to trigger real-time supports including adaptive prompts or teacher alerts [5, 6, 25]. These works emphasize that observed (low) performance can reflect multiple latent causes (e.g., low effort, unproductive strategies) that can be detected by various engagement signals. Studies have also explored engagement-sensitive tutoring and motivational supports within tutors. For example, Arroyo et al. [4] proposed and evaluated effort-based tutoring that infers effort from behavior and adapts activity selection accordingly. Similarly, the AnimalWatch ITS modeled student performance based on prior effort and observed learning gains from use [8].

However, much of the literature operates at the level of problem-steps, sessions, or within-day interactions, and often evaluates detectors or interventions in-situ [25]. In contrast, many educational decisions about pacing, check-ins, and expectations occur on weekly rhythms (e.g., weekly assignments, classroom schedules, weekly reflections). Our work complements fine-grained engagement modeling by introducing and benchmarking a *week-ahead forecasting* task: predicting next-week outcomes from prior logs. This framing targets longer-term engagement rather than moment-to-moment disengagement detection.

2.2 Motivation, Self-Efficacy, and Persistence

Motivational theory provides a lens for why learners persist (or fail to persist) even when instructional support is available. Self-determination theory emphasizes the roles of competence, autonomy, and relatedness in sustaining motivation [40]. Goal-setting theory further argues that specific and challenging goals can mobilize effort, but only when goals are perceived as attainable; repeated failure can undermine perceived competence and persistence [34, 35]. This also aligns with accounts of vicious cycles in learning, where recent success and failure experiences can compound over time, shaping subsequent engagement and outcomes [51].

Empirically, motivational constructs such as self-efficacy have also been studied in learning contexts, including variability over time and relations to behavior and performance. For example, Bernacki et al. assessed self-efficacy and found that efficacy varied reliably during learning and predicted subse-

quent help-seeking and performance [10]. These perspectives motivate our week-ahead targets in two ways. First, they suggest that effort and persistence are not static traits but can fluctuate with recent experiences and context, making forecasting meaningful at intermediate time scales (e.g., week-ahead). Second, they motivate evaluating forecasting not only as an error-minimization exercise, but as a foundation for decision-support while preserving learner agency. Importantly, our contribution is not to measure motivational states directly. Instead, we forecast behavioral and progress outcomes that are plausibly influenced by such dynamics, and we interpret feature patterns in light of these theories.

2.3 Student Behavior Prediction in EDM

Prior work in EDM has extensively modeled various prediction targets, but along dimensions that differ from our engagement forecasting task. For example, much of the ITS-focused literature operates at fine temporal granularity (problem-step or within-session windows), predicting affective states such as concentration, boredom, or frustration [7, 53], and detecting behaviors such as gaming the system or off-task activity. These studies typically define engagement as an affective construct (Engaged Concentration) inferred from ITS interaction traces, and the tasks are framed as supervised binary classification aimed at real-time intervention. A related line of work is interested in modeling effort and progress in terms of detecting wheel-spinning, defined as prolonged amounts of time students spend on a problem without achieving mastery [54, 49]. Wheel-spinning work examines on progress by identifying when effort is unproductive because it fails to translate into learning gains. However, such work still focuses on opportunity-to-mastery sequences rather than calendar-time horizons. On the other hand, predictions tasks are also common in MOOC and VLE settings, where models forecast dropout or stopout using aggregated clickstream features [21, 50, 23]. However, these tasks are also generally classification problems centered on retention rather than continuous behavioral effort or learning progress within an ITS. Classic learning-rate and difficulty models (e.g., AFM, BKT, and related extensions) estimate latent learner and item parameters from practice histories, but they are typically not framed for supervised forecasting of observable engagement indicators [15, 18].

At the same time, prior work has shown that effort-related measures—particularly time-on-task—can meaningfully predict learning outcomes, even when imperfect. For example, prior EDM studies have used time-on-task as measure of engagement to predict achievement and learning gains [39]. Although time-on-task has known limitations and should not be treated as a perfect proxy for learning [32], it remains practically valuable because it is simple and directly observable by tutors and students. For example, middle school students find it easier to express goals in time-on-task minutes than in progress metrics such as skill mastery [38]. Many educational platforms and vendors also recommend minimum weekly usage targets (e.g., 30 minutes) [24], and in settings without detailed skill models, time-based measures may be the only consistently available indicator of effort (and arguably more comparable than the number of completed problems, which may vary in complexity across platforms). Therefore, defining effort as minutes practiced provides a straightforward, usable signal for week-to-week decision support.

While prior work on affect detection, wheel-spinning, and weekly dropout prediction offers methodological inspiration (e.g., supervised machine learning (ML) models) [2], these approaches do not address the same prediction target, temporal granularity, or prediction environment (ITS). In contrast, we introduce engagement forecasting as a supervised, week-ahead regression task within an ITS predicting two observable outcomes: minutes practiced (effort) and new skills mastered (progress). This framing allows engagement forecasting to consider broader student context across time rather than step-level details, which practically situates predictions as week-to-week decision-support signals for tutors and students. Furthermore, through interpretability analysis, continuous prediction of weekly student trajectory provides theoretical insights into longer-term predictive factors (e.g. student behaviors over several weeks) that prior EDM works with fine-grained measures rarely look at.

Additionally, as prior prediction works are not directly applicable in our forecasting setup, we borrow work from Adams et al. [1] in the adjacent health behavior domain to provide a reasonable, non-naive baseline against our ML models. Adams et al.'s algorithm recommends a daily step target by looking at a person's last 9 days of step counts and setting today's target to the 60th percentile. However, while this heuristic algorithm is easily implementable, its transferability across domain (health to education) and time granularity (days to weeks) is an open question, and its heuristic nature may provide insight into whether or not statistical features actually bring more predictive power.

3. DATASET

We focus on ITS as a seminal paradigm of adaptive learning systems [47]. We use a longitudinal dataset available upon request [20] from students using web-based ITS for middle school mathematics. The dataset comprises activity logs collected from 425 students over 39 weeks (October 2010 to May 2012), capturing 2.9 million student-problem interactions. Students engaged with the system for an average of 39.8 ± 14.7 minutes per week, solving an average of 24.7 ± 13.1 problems weekly. Individual student-week observations ($n = 11{,}710$) showed considerable variability in engagement, with weekly practice time ranging from zero to over 6 hours (mean = 43.2 ± 25.9 minutes per student-week). The raw dataset contains 33 columns including: anonymized student identifiers, precise timestamps, interaction durations, learning outcomes, knowledge components, opportunity counts, and problem identifiers [20]. This event-level granularity enables aggregation of individual interactions into weekly summaries. While our dataset is from 2012, it remains relevant to modern ITS usage context. In particular, fundamental tutor features in ITS remain the same (adaptive step-level guidance with feedback and hints, adaptive problem selection [46]). Data format also remains the same (e.g., through DataShop log data standards [44]).

The unit of analysis for our engagement forecasting task is individual student-weeks. ITS automatically tracks two key outcomes: (1) time spent on practice problems and (2) whether related skills were mastered. We generate weekly ground-truth data for both minute and skill targets by: (1)

aggregating time and skill data by ISO weeks (Monday–Sunday), creating identifiers such as "2011-W23;" (2) summing interaction durations per student-week to create the first prediction target *minutes practiced per week*; (3) Tagging a skill (knowledge component) as mastered when the AFM predicts proficiency >0.95 for a student-skill pair [15]; (4) Counting the number of new skills mastered per student-week to create the second prediction target *new skills mastered per week*; (5) Filtering missing and invalid values and removing outliers with Tukey's Fence ($k = 1.5$).

We describe the four categories of features we created below. The detail of the entire feature set is described in Table 1.

3.1 AFM-derived Features

We adopt the AFM to derive interpretable features with respect to the learners [15]. AFM models the probability that student i answers a problem step j correctly as:

$$\Pr(Y_{ij} = 1) = \text{logit}^{-1}\left(\theta_i + \sum_{k=1}^{K} q_{jk}\,\beta_k + \sum_{k=1}^{K} q_{jk}\,\gamma_k T_{ik}\right),$$

where Y_{ij} is student i's response on step j, θ_i represents student ability, β_k is skill easiness, γ_k is the learning rate for skill k, T_{ik} is the number of prior opportunities student i has had on skill k, and $q_{jk} \in \{0, 1\}$ indicates whether step j requires skill k [16]. AFM explains performance as three additive components: (1) baseline student ability (θ_i), (2) learning gained with additional opportunities ($\gamma_k T_{ik}$), and (3) the easiness of practiced skills (β_k). Because these terms are interpretable, we map them directly into features for engagement forecasting. Specifically, we derive *student ability* from θ_i, *student learning rate* from $\gamma_k T_{ik}$, and *student week difficulty* from the negative weighted average of β_k across skills practiced in one student-week, weighted by the number of encounters T_{ik}. We recompute AFM parameters on a rolling five-week window, extracting updated student-level ability, learning rate, and difficulty values each week.

3.2 Other Feature Groups

Beyond AFM, we engineered additional feature groups to capture complementary aspects of student engagement and performance. In general, we categorize the features into four groups for reference in analysis: (1) AFM-style learner features, (2) engagement activity, (3) practice gaps, and (4) prior achievement.

Engagement Activity. We include basic engagement measures (minutes practiced, problems solved, opportunities, and skills along with their lagged values. From these sequences, we derive changes, averages, and variability statistics. These features serve as intuitive baselines, capturing both immediate performance and historical trends.

Practice Gaps. Zeros in weekly minutes are treated as informative rather than missing values. Because 98% of students exhibit at least one temporal gap, and the average student has four gaps, we encode gap patterns through features such as recent gaps, time since the last gap, and cumulative gap count. These indicators capture disengagement episodes that could influence future engagement.

Prior Achievement. Prior achievement is a strong predictor of future learning outcomes [26]. We therefore include features capturing initial performance (quartile of early skills), stability of performance (consistency score), and improvement from early to later weeks. These serve as proxies for student preparedness and trajectory.

Table 1: Overview of feature groups and individual features.

Feature	Description
AFM	
student_ability	Baseline performance
student_learning_rate	Improvement per opportunity
student_week_difficulty	Weighted average difficulty of done skills
Engagement Activity	
minutes_current	Minutes practiced this week
minutes_lagk	Minutes practiced up to k weeks back
problems_current	Problems solved this week
problems_lagk	Problems solved up to k weeks back
opportunities_curr.	Opportunities tried this week
opportunities_lagk	Opportunities tried up to k weeks back
skills_current	Skills estimate this week
skills_lagk	Skills estimates up to k weeks back
recent_change_*	Week-to-week and average changes (minutes, problems, skills)
minutes_stats	Summary statistics (mean, std, range, iqr) of minutes practiced
problems_stats	Summary statistics (mean, sum, std) of problems solved
Practice Gaps	
has_recent_gap	Indicator of zero-minute weeks recently
weeks_since_gap	Number of weeks since the last zero
gap_count	Total number of zero-minute weeks
Prior Achievement	
start_quartile	Quartile of initial skills
consistency_score	Stability of skills relative to its mean
improvement	Change in skills from early to later weeks

4. METHODS

Our methods comprise four steps. First, we describe our ML models and their training procedure. Second, we define model evaluation metrics and the model selection process for engagement forecasting that can most generalize out of sample. Third, we describe interpretability analysis conducted on the four feature groups. Finally, we describe the protocol for carrying out our exploratory case study.

4.1 Model Training

For each student i and week t, we construct a feature vector $x_{i,t}$ (described in Table 1) from the student's interaction history up to week t. We train separate models to predict next-week outcomes:

$$y_{i,t+1}^{(\text{min})} = \text{minutes practiced in week } t+1$$
$$y_{i,t+1}^{(\text{skill})} = \text{new skills mastered in week } t+1.$$

Thus, each sample is a one-step forecast, and sequential forecasts across weeks yield predicted engagement trajectories.

We benchmark fifteen predictors spanning heuristic and supervised approaches. As simple temporal baselines, we im-

plement: (1) last week's value carried forward; (2) median across all past values for the same student; (3) median across non-zero past values; (4) mean across all past values; and (5) mean across non-zero past values. The "non-zero" variants follow prior design by Adams et al. [1] and potentially avoid ambiguity: a zero entry may indicate either disengagement or simple absence. These baselines establish a lower bound for performance with naive statistical heuristics. We also adapt three percentile-based heuristics from prior work in health behavior change [1, 13]. These set the target at the (6) 50th, (7) 60th, or (8) 70th percentile of the most recent nine non-missing values, enabling us to examine whether the original 60th-percentile assumption holds when transferred from health to education. Because the original algorithm requires sufficient history, we design a staged initialization procedure. In week 1, the prediction is set to the dataset average. In week 2, the prediction equals the student's week-1 performance plus the gap between the dataset's 50th and 60th percentile in week 1. From week 3 onward, until sufficient history is available, the prediction is updated as 60% of the way toward the highest of the student's previous values. This approximates "somewhat above average" performance under limited history, aligning with engagement theory [48].

Beyond these eight baselines, we benchmark seven supervised learning methods that leverage the full engineered feature set: (9) Random Forest (RF), (10) XGBoost (XGB), (11) Ridge regression, (12) LASSO regression, (13) linear regression (LR), (14) multilayer perceptron (MLP), and (15) long short-term memory (LSTM) network. This suite of models was chosen to span a spectrum of inductive biases—linear vs. nonlinear, tree-based vs. neural, memoryless vs. sequential—thereby probing which paradigms best forecast student engagement. All implementations use standard off-the-shelf libraries to ensure reproducibility, and the full pipeline is available in a public repository[1].

4.2 Model Evaluation

We evaluate generalization to new students by using student-level splits. We allocate 70% of students for model development and hold out the remaining 30% of students for final testing, ensuring no student appears in both sets. Within the 70% development set, we conduct 5-fold time-series split for model selection. For each student, predictions are produced in chronological order, always using information available up to the current week.

We report MAE for interpretability. We also report relative error reduction:

$$\Delta_{\%} = \frac{\text{MAE}_{\text{compared model}} - \text{MAE}_{\text{model}}}{\text{MAE}_{\text{compared model}}} \times 100\%.$$

To test significance, we estimate 95% confidence intervals via paired bootstrap resampling over students ($B = 10{,}000$).

To answer **RQ1**, we evaluate models across four settings for each model hyperparameter and five history window lengths (the number of past weeks a model can see) to (1) investigate how well ML approaches forecast engagement, and (2) provide empirical analysis of what configurations and model families affect the performance gains of ML models. We then select the best-performing configurations for subsequent analysis. To answer **RQ2**, we compare weekly performance trends of our best ML model against the three Adams predictors on the remaining 30% holdout set. We examine whether the 60th percentile assumption aligns well with student behavior trends and analyze where data-driven models excel in cases where Adams do not generalize.

[1]https://github.com/EricQiu6/EngagementForecasting

4.3 Feature Importance Analysis

To address **RQ3**, we use feature importance measures to examine which information derived from ITS logs is most indicative of future engagement levels. For linear models (Ridge, LASSO, Linear Regression), importance is the absolute value of coefficients, indicating how strongly each feature relates to the target [28, 45, 43]. For tree ensembles (Random Forest, XGBoost), importance comes from impurity-based criteria, i.e., how much each feature reduces prediction error in splits [27, 17]. To make results comparable, we average importances across validation folds and normalize them to sum to one. We then group features into the four categories and compute average weights for each group. This shows whether predictive gains come mainly from AFM-style learner parameters, engagement activity, practice gaps, or prior achievement.

On top of attribution, we conduct ablation study on the models to test whether feature groups are *necessary*. For each group, we remove it and retrain the models, holding all other conditions fixed. We then compare MAE to the full model, estimating contribution of the excluded group. Bootstrap resampling across students provides confidence intervals and significance tests for these error differences.

4.4 Studying Tutors' Use Of Signals

We conducted a semi-structured qualitative user interview case study to outline how the model signals we investigated (e.g. learning rate, difficulty, consistency) may inform real-world tutoring. The study protocol was approved by our Institutional Review Board (IRB), and all participants provided informed consent and received compensation for their time. Participants (N = 8 college students doing part-time K–12 math tutoring online) interacted with a goal-setting dashboard across four scenarios. This sample size aligns with comparable educational design research [12] and was guided by qualitative saturation, as few new themes emerged in later interviews. Each scenario varied by goal type (minutes practiced vs. skills mastered) and alignment with tutor intuition (intuitive vs. counter-intuitive) to examine how tutors interpret and respond to explainable features that may conflict with the tutors' initial judgement. The dashboard displayed recent goal cycles, achieved vs. target progress, and a system recommendation panel with three settings: (1) no recommendation, (2) recommendation of a goal value only, and (3) recommendation with a justifying explanation that cites relevant features extracted from our statistical models. We designed this three-variants setup to respectively (1) capture each tutor's baseline judgment without any recommendation influence, (2) measure how a recommended value alone shifts tutor decisions, and (3) isolate the incremental effect of the explainable features beyond the system recommendation itself. Scenarios and explanation variants were presented in randomized order. See Fig. 1 for example dashboard interfaces. The study was descriptive and did not measure learning outcomes; it aimed to

Table 2: MAE summary for minutes and skills. Lower is better. Top feature-augmented model (XGBoost) vs. average of eight baselines.

Target	Baseline MAE	Top Model MAE ($\Delta_{\%}$)
Minutes/week	*10.37*	*8.05 (−22.4%)*
New skills/week	*5.21*	*3.51 (−32.6%)*

characterize tutor interpretation and decision behavior when explanations reference the interpretable features, thus clarifying whether the forecasting signals could be helpful and used in downstream tutoring scenarios. We collected qualitative think-aloud data to capture tutors' mental models and decision-making processes.

5. RESULTS

We first test how accurately feature-based models forecast next-week engagement and which settings affect these gains. Next, we check whether percentile heuristics from other domains transfer to weekly K–12 engagement by comparing Adams baselines against our best ML model. Then, we assess which feature categories drive performance by analyzing importance scores and ablation results for AFM-based features, engagement activity, practice gaps, and prior achievement. Finally, we examine the eight case study sessions to interpret our explainable features in context of downstream tutor understanding during goal setting.

5.1 RQ1: forecasting effort and progress

Performance gains over baselines. Data-driven ML models substantially outperform heuristic baselines (last value, mean/median variants, and Adams-style methods [1, 13]). On average, error falls by **22%** for minutes and **33%** for skills. Bootstrap confidence intervals on paired percentage differences exclude zero across linear, tree, and neural families, establishing that improvements are statistically significant. To better understand where these gains come from, we next compare across model family and hyperparameters.

Family-level differences. As shown in Table 3, family-level comparisons reveal only modest variation. For the **minutes** target, linear vs. tree shows a non-significant MAE gap (mean diff = 0.16; 95% CI [−0.07, 0.40]; $p = .318$; Cliff's $\delta = 0.08$). However, while linear and tree models outperform neural nets at shorter histories, this gap narrows to non-significance as history length increases past 20 weeks, consistent with neural nets' higher data requirements. For the **skills** target, all pairwise comparisons yield negligible differences (e.g., linear–tree mean diff = 0.02, CI [−0.13, 0.16], $p = .362$, $\Delta_{\%} = 0.03$), with effect sizes $|\delta| \leq 0.07$. Thus, model family matters somewhat for minutes under short histories, but practical differences vanish for skills.

Hyperparameter sensitivity. Within each family, performance varies little across hyperparameter settings. Friedman tests blocking by window×fold show low and nonsignificant concordance (Kendall's $W < .05$), with no configuration emerging as a consistent winner. Accuracy is robust to parameter choice; most reasonable configurations yield errors within a narrow range.

Table 3: Pairwise family comparisons by target (MAE and $\Delta_{\%}$ between the row model and the comparator). Lower is better. **Bold** marks significance. * $p < .05$; ** $p < .01$

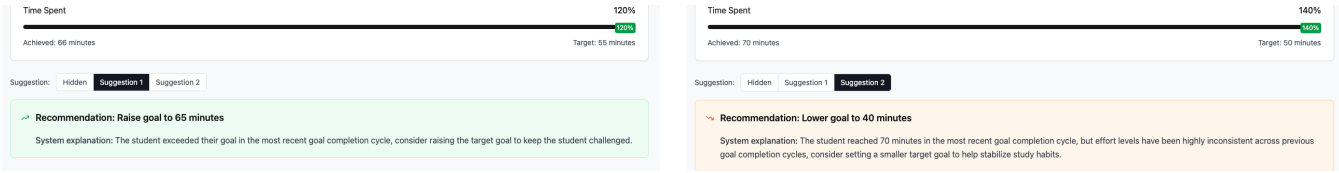
(a) Skills

Family	Models	MAE	vs.Tree	vs.Linear	vs.Neural
Linear	LR,Ridge,LASSO	3.60	0.02	–	-0.11
Tree	RF, XGB	3.50	–	-0.02	-0.13
Neural	MLP, LSTM	3.68	0.13	0.11	–

(b) Minutes

Family	Models	MAE	vs.Tree	vs.Linear	vs.Neural
Linear	LR,LASSO,Ridge	9.04	0.16	–	**-1.72****
Tree	RF, XGB	8.76	–	-0.16	**-1.88****
Neural	MLP, LSTM	9.46	**1.88****	**1.72****	–

Takeaway. Data-driven models greatly outperform baselines by 22–33% (Table 2). However, the decisive factor for performance gains is not which family or hyperparameter is chosen. Linear, tree, and neural families all reach similar accuracy given sufficient history, and hyperparameters rarely alter the outcome. On practical grounds, we adopt **XGBoost** as a default model: it performs best empirically, trains efficiently, and provides directly interpretable attributions for downstream analyses.



5.2 RQ2: do heuristic rules generalize

We evaluate Adams-style percentile heuristics [1, 13] against our chosen feature-based predictor XGBoost. These heuristics predict engagement through a fixed percentile (e.g., 50th, 60th, 70th) of past performance. The >50th-percentile rules assume *continuous improvement*: if learners repeatedly meet their targets, the prediction will continue to increase.

Fig. 2 shows that this assumption does not hold in our setting. Effort (minutes practiced per week) engagement stabilizes after an early surge, and progress (new skills mastered per week) rises initially but then declines mid-semester. As a result, Adams predictors systematically overshoot: P60 and P70 in particular perform 4–33% worse than P50 across targets, and averaging across percentiles further degrades accuracy. Table 4 shows full performance results.

XGBoost reduces MAE by 20–30% relative to Adams-P50, and by larger margins relative to Adams-P60 and P70 (Table 4). Still, its performance in the earliest weeks is weaker, and for the skills target, it tends to underpredict systematically. The spread bands in Fig. 2 help explain this pattern: the dataset exhibits far greater instability early in the semester. This higher variance reduces the stability of any predictor and plausibly explains why XGBoost lags in early weeks and underestimates peaks in skills. Once trajectories stabilize starting week 9, XGBoost outperforms Adams predictors by even larger margins and tracks both effort and progress levels much more closely.

Takeaway. Percentile-based heuristics from other domains do not transfer cleanly to weekly K–12 practice. Their built-in continuous improvement assumption becomes inaccurate once growth slows, leading to systematic overprediction. A feature-based model like XGBoost not only avoids this pitfall

(a) (b)

Figure 1: (a) **Intuitive goal-setting scenario (minutes practiced).** Example of an intuitive case that raises goal because student exceeded prior week's goal. (b) **Counter-intuitive goal-setting scenario (minutes practiced).** Example of a counter-intuitive case that lowers goal even though the student exceeded prior week's goal, citing the consistency feature as reason.

but adapts better to shifting regimes in the data, providing substantially more accurate predictions given sufficient data.

5.3 RQ3: which features are most indicative

The top–k feature plots (Fig. 3) show two patterns, with calibrated strength. For **effort** (minutes practiced), the top features are primarily driven by *recent engagement activity*: *minutes mean*, *current minutes per week*, and a short lag *target lag 4* take three of the top four slots; additional lag features also appear in the top–11 (*minutes per week lag 16*, *target lag 16*, *total opportunities lag 16*). However, stability across model families is low: linear and tree models rank features differently (Kendall's $\tau \approx 0.28$), and category-level agreement is nearly zero ($\tau < 0.01$). In short, effort is driven mainly by *recent engagement activity*, with smaller contributions from learner modeling.

For **progress** (skills mastered), the key features are *learner-centered* indicators: *current student ability*, *performance consistency score*, and *current student week difficulty* occupy three of the top four positions. Crucially, this ordering is more stable across model families: per–feature consistency is moderate ($\tau \approx 0.37$) and the category–level consistency is strong ($\tau \approx 0.67$). We therefore conclude that progress engagement is shaped mainly by *learner-centered signals* that are robust to choice of model family, whereas effort reflects a recent-activity-driven but family-sensitive mixture of engagement activity and learner modeling.

Ablation tests (Table 5) confirm these patterns. For **minutes**, removing AFM, practice gaps, or prior achievement features causes only small losses ($< 1\%$), while recent engagement activity captures nearly all accuracy (differences versus the full set are $< 0.3\%$). For **skills**, every group contributes: dropping engagement activity features yields the largest loss ($> 1\%$), but AFM, gaps, and prior achievement features also provide meaningful differences (0.6–0.8% each). Taken together, these results align with conclusions drawn from the feature rankings: effort forecasts are recent-activity-led, while skills forecasts rely more on learner-centered signals.

5.4 Case Study Results

We examined how eight tutors interacted with system generated recommendations and accompanying explanations that referenced distinct feature types identified in RQ3. Two independent coders conducted thematic analysis of the think-aloud data. We describe our derived patterns below.

First, tutors consistently preferred rationales backed by multi-week historical data. One participant noted, "Past data… tendency… really convinces me." This aligns with our statistically driven prediction approach, suggesting that, beyond the prediction values, the derived explainable features themselves may be valuable in downstream settings to assist in tutoring decision-making.

Second, tutors' mental models diverged by target type in a way that mirrors our prediction target split. For effort (minutes), tutors emphasized routine formation and sustainable baselines, consistent with recency-driven engagement dynamics (e.g., lags, recent change, and variability). For progress (skills), tutors more often reasoned about learner and content properties (e.g., ability, consistency, and difficulty), which matches our feature-importance pattern where AFM-derived ability and week difficulty are central.

Third, tutors expressed skepticism toward difficulty and ability claims unless the definition was clear. In addition, a few tutors raised concerns about sensitivity around student-facing explanations. For example, one participant remarked, "If the words say… 'low learning rate', I don't think that's a good thing to show kids." These critiques reinforce a key design implication for deploying model-derived signals as explainable evidence: even when predictions may be accurate, their impact depends on careful communication that preserves learner agency and avoids discouragement.

Lastly, when qualifying tutor acceptance and trust, we find that participants generally prefer to take final control of the specific goal value. However, across the 2x2 scenario split by goal type (minutes practiced vs. skills mastered) and intuition (intuitive vs. counter-intuitive), all tutors are most influenced by the third explanation variant that provided additional feature-backed evidence. In particular, one response characterized the tutors' trust: "if the system… takes the history of students, and it suggests based on that history, then I think I would be totally okay to use the suggestion of AI." Together, these findings show that while tutors preferred to retain final say, they trusted the explainable features, finding the system helpful in designing plans with their student. These feedback suggest that explainable signals may have the potential to aid decision-making in human-AI tutoring.

Overall, the tutor sessions help interpret our modeling results: the signals that are most predictive (recent history for effort; learner ability and difficulty for progress) are also the signals tutors find most helpful. This alignment between the signal's predictive power and tutor reasoning suggests that engagement forecasting offers a foundation for utilizing ex-

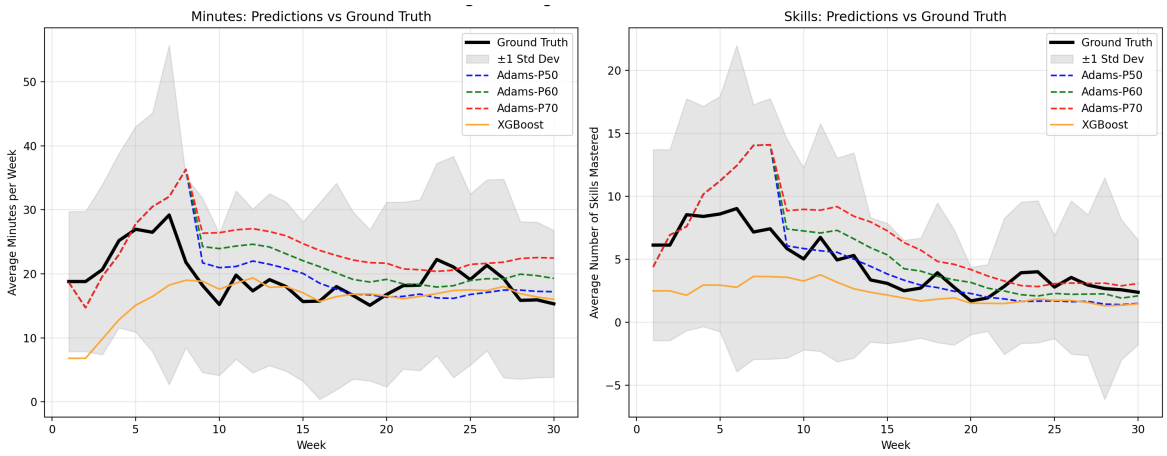


Figure 2: Average minutes and skills per week across all students plotted against the predictions of different models, also averaged across students (XGBoost, 50th percentile, 60th percentile, and 70th percentile variants of Adams predictor). Grey band is the standard deviation spread of the ground truth data.

plainable contextual information to support timely instructional decisions, which may in turn lead to more calibrated and consistent engagement plans for students.

6. DISCUSSION

The present study is motivated by a persistent challenge in ITS: students often do not practice consistently enough to fully realize the system's potential learning gains, even within scheduled classroom time [25, 22]. While EDM has made major progress in modeling knowledge and performance, comparatively less work has treated effort across weeks as primary analytic targets [21, 37]. Our contribution is formalizing and benchmarking *engagement forecasting* as a novel supervised learning task over ITS log data. This empirical contribution (forecasting and feature analysis) makes patterns of sustained engagement visible and explainable, supporting its potential as a decision-support tool for teachers and students to construct more calibrated and personalized plans for effective and consistent engagement.

The remainder of this section is organized by research question. For each RQ, we recap key results, then interpret its significance in the context of prior work, draw implications for EDM and educational practice, and outline directions for future work. We conclude with analysis of our case study to connect engagement forecasting to real-world settings.

6.1 Forecasting suggests practical viability

Answering **RQ1**, feature-driven models achieve sizeable reductions in forecasting error—approximately 22% for minutes practiced and 33% for new skills mastered—relative to multiple heuristic baselines [1]. Notably, performance is similar across linear and tree-based families, and hyperparameter differences are small once sufficient history is available. This convergence suggests that, for engagement forecasting, data coverage and feature design may matter more than selecting a particular model class. Practically, this model insensitivity is encouraging: systems can deploy relatively standard models (e.g., gradient-boosted trees or regularized

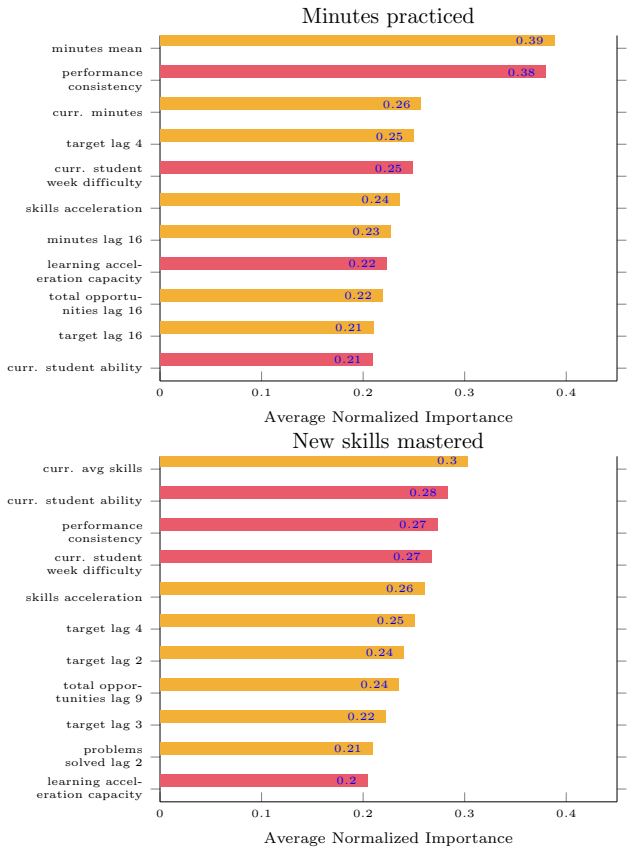

Figure 3: Feature-importance rankings. Red: learner-centered; orange: recent activity. Top: minutes; Bottom: skills.

regressions) and still obtain large improvements over heuristics, lowering barriers to adoption. Notably, although we demonstrate that our data-driven approach is successful at improving future effort and progress prediction, we do not claim that this exact model or feature stack generalizes to other contexts due to varying engagement dynamics. Instead, we offer open-source code to apply our models to local data and ensure that features are available and meaningful with respect to the class dynamics [25].

Crucially, improved forecasting accuracy alone does not imply improved learning outcomes. Rather, week-ahead predictions are best interpreted as **decision-support signals**. For example, forecasts can flag students whose engagement may deviate from recent patterns, while still leaving room for instructors and tutors to situate the forecasts using contexts the system cannot access, such as classroom constraints, instructional goals, and students' schedules. In this case, a tutor might discuss with a student any upcoming events that would get in the way of normal engagement. Such interaction helps refine engagement expectations and makes predictions more useful for week-to-week support.

6.2 Transferred heuristics do not match

Answering **RQ2**, percentile heuristics adapted from adjacent health behavior domains [1, 13] do not generalize cleanly to K–12 weekly trajectories. Percentile rules that target above-median performance systematically overshoot, with P60 and P70 performing worse than P50 across targets, and our feature-driven model outperforming P50 by 20-30%.

Table 5: Ablation results. MAE (lower is better) and relative change $\Delta_{\%}$ vs. *Full*. Bold $\Delta_{\%}$ indicates bootstrap CI on the paired difference excludes 0 (significant).

Condition	Skills		Minutes	
	MAE	$\Delta_{\%}$	MAE	$\Delta_{\%}$
Full (reference)	4.1904	0.00%	9.3067	0.00%
Base features only	4.2151	**0.59%**	9.3226	**0.17%**
Base + activity	4.2355	**1.08%**	9.3082	0.02%
Base + gaps	4.1996	**0.22%**	9.3125	0.06%
Base + prior	4.2173	**0.64%**	9.3188	0.13%
Base + AFM	4.2129	**0.54%**	9.3286	**0.24%**
All except activity	4.2300	**0.95%**	9.3088	0.02%
All except gaps	4.2141	**0.57%**	9.3155	**0.09%**
All except prior	4.2239	**0.80%**	9.3111	0.05%
All except AFM	4.2180	**0.66%**	9.3122	**0.06%**

Our analysis shows that such percentile heuristics does not reflect typical ITS usage patterns over a school year. Factors such as limited instructional time, schedule disruptions, and shifting curricular focus mean that consistently exceeding past performance is neither realistic nor always desirable [25]. This observation seems consistent with prior work [25, 22] showing large variations in how students use available time—the limited ability for a single heuristic to model all students may in part explain its lower prediction accuracy. In contrast, feature-based forecasting is more flexible: it can represent plateauing, regression, and regime shifts as a function of learner model (AFM), recent activity, inactivity patterns, and prior achievement. This flexibility is likely necessary for realistic decision support in classrooms with limited time and schedule disruptions.

6.3 Effort and progress have distinct drivers

Answering **RQ3**, our interpretability analyses reveal a consistent distinction between the two targets. **Effort** (minutes practiced) is driven by recent engagement activity, while **progress** (new skills mastered) depends more strongly on learner-centered signals such as AFM-derived ability and difficulty, as well as consistency. AFM features may not always be available in adaptive learning systems [19, 3]. Still, simplified measures of content difficulty or student ability estimated from past students' pass rates could still be used in other models. Alternatively, our ablation study suggests these features could also be removed while retaining viable model performance. In addition, data-driven modeling is weaker in the starting weeks for both targets. Nevertheless, since results show that XGBoost widens the performance gap against baselines starting week 9, one mitigation strategy may be to employ the same initialization procedure in the starting weeks as we constructed the Adams predictors (see Section 4.1) [1, 48].

The divergence between the sets of predictive signals for effort vs. progress seems theoretically counterintuitive, since learning progress ultimately arises through effort. While investigating a satisfactory explanation is beyond the scope of

this work, we hypothesize that the definition of progress in terms of weekly skills mastered may be too coarse-grained. That is, the progress-effort relationship may be obscured by discrete skill mastery, whereas classical measurements of proficiency (e.g., AFM, BKT) operate at a step-level [15, 18]. Nevertheless, defining progress as skills mastered is practically valuable as it is more aligned with this work's intention to view predictions as week-to-week decision-support signals for tutors and students. Furthermore, the separation of targets is useful for practical downstream use cases. By comparing feature groups, we aim to isolate which signals most predict student persistence and to potentially translate these insights into improved ITS adaptivity—for example, adjusting difficulty in mastery-based problem selection receptive to student motivation and effort [52]. These signals may also provide explanatory insights to learner and teacher feedback in downstream applications. We expand on this in the next case study section.

6.4 Implications for Explainable Interfaces

Across the case study, three observations were most consistent: (1) when judging recommendations, tutors placed high trust in system explanations backed by the explainable features when their definition and data source (weeks of personalized student data) were clear; (2) tutors reasoned differently about effort vs. progress in ways that mirror our target-specific feature drivers; and (3) tutors identified sensitivity concerns of learner-modeling claims (e.g., difficulty and ability) when recommendation becomes student-facing.

Together, these findings suggest that the top features extracted in RQ3 (e.g. ability, difficulty, consistency) are not only predictive inputs but also candidate explanatory evidence. We identify feature groups that map naturally onto the kinds of reasons tutors use, while also revealing that practical explainability may break down if the sources of the features are unclear (i.e. tutor confusion about definition of ability and difficulty). These findings suggest that grounded and clearly defined features may be practically compatible with existing tutor reasoning workflows, situating feature analysis as more than a post-hoc interpretability exercise.

While we find that the features themselves may provide helpful explanatory power to decision making in downstream contexts such as goal setting, the direct usage of the engagement prediction values in these applications should be further scrutinized. For example, accurate week-ahead predictions might not determine appropriate goals. In particular, while a model may predict declining engagement accurately, it is not clear whether using declining value as goal recommendation is optimal for student motivation. One promising direction of work could define and test explicit forecast-to-recommendation mappings that balance challenge and motivation while incorporating pedagogical constraints (e.g., schedule disruptions, shifting curricular focus, and teacher-configured limits). This would close the loop from prediction to intervention and enable in-situ evaluation of downstream outcomes, including tutor adoption, student acceptance, and learning gains.

6.5 Limitations and Future Work

A few limitations bound the generalizability of our findings. The study is restricted by a single ITS, subject domain, as well as platform-specific logging; some inputs underpinning our features (e.g., opportunity counters, fine-grained timestamps, skill tags for AFM) are not universal and may require proxies or simplified learner-state estimates when absent. External validation should therefore include cross-site replication and leave-site-out testing. In addition, we do not distinguish between classes that assign homework and those that do not, even though these contexts differ in how student agency and self-regulated learning operate [42, 9]. Future work could explicitly examine how forecasting performance and interpretation differ across instructional contexts. Finally, an open design question is how to communicate forecasts effectively. Prior research on open learner models and explainable learning analytics suggests that transparent representations of learner state can support self-regulation [14, 30]. Translating forecasts into actionable feedback without discouraging learners requires careful design and communication. While we motivate towards this direction with our case study, such work is beyond the scope of this paper and may be a valuable next step.

Several open questions about the prediction task itself also merit further investigation. Our contribution is the formulation and empirical validation of week-ahead engagement forecasting using standard ML methods. We leave algorithmic innovations on this prediction task for future works. In particular, further insights into which features are predictive and how accurate student engagement can be modeled may be valuable. Relatedly, both of our targets—minutes practiced and new skills mastered—are useful but imperfect proxies for effort and learning progress [32]. Alternative proxies—including problem attempts, session frequency, and active-vs.-idle time—were not directly compared in this work. As prior research show that students naturally articulate goals in both problem-count and time-duration terms [38], a comparative study of proxy choice as the forecasting target is a natural next step.

Looking forward, engagement forecasting may support a wider range of applications than goal setting alone. Potential uses include instructional pacing and estimating time-to-mastery under revised content—contexts where week-by-week forecasts could inform planning even without direct student-facing interventions. Evaluating such usages, and studying how forecasts interact with teacher-student decision-making, remains an important area for future research.

7. CONCLUSION

Prior work in EDM has introduced statistical learning methods to predict important targets such as learning, affect, momentary disengagement, performance, and dropout. However, comparatively little work has focused on explainable forecasting of student effort and progress at a weekly timescale, aligned with practical instructional decision-making related to practice goal setting. In this paper, we introduce engagement forecasting as a novel prediction task in ITS and benchmark models for forecasting two observable outcomes: minutes practiced per week (effort) and new skills mastered per week (progress).

First, as a methodological contribution to EDM, we showed that statistical learning models are well suited to this task, yielding 20–30% reductions in forecasting error relative to

heuristic baselines transferred from other behavioral domains. Our results further demonstrate that data-driven models better capture non-monotonic patterns common in real classroom distributions. Second, through interpretability analysis, we provided theoretical insight into the structure of engagement, showing that effort and progress are driven by qualitatively different features. Future effort is driven by recent engagement activity, whereas future progress depends more on learner-centered signals such as ability, difficulty, and consistency. These findings contribute insights into the features that learners need to consider to effectively calibrate their effort, a dimension rarely supported in adaptive learning systems. Third, through a semi-structured tutor interview, we examined how these predictive signals are interpreted in downstream goal-setting contexts. We found that tutors reason differently about effort vs. progress in ways that align with our findings, suggesting that the signals identified through engagement forecasting are not only predictive but also meaningful for constructing more personalized plans for effective and consistent engagement. While this study does not evaluate learning outcomes, it provides a foundation for future work linking engagement forecasts to classroom learning benefits, given prior evidence that time-on-task and related effort measures can be predictive of learning outcomes in tutoring software [39]. This foundation enables future work that explicitly links forecasts to goal-setting strategies and instructional planning, evaluated on recommendation acceptance, persistence, and learning outcomes.

8. ACKNOWLEDGMENTS

This research was primarily funded by the Institute of Education Sciences (IES) of the U.S. Department of Education under award #R305A220386 and was partially supported by the National Science Foundation under Award No. 2349558. This work was supported, in whole or in part, by the Bill & Melinda Gates Foundation INV-068909. ABSTRACT

Hybrid human-AI tutoring, where technology and humans jointly facilitate student learning, can be more beneficial than AI-only tutoring. However, preliminary evidence suggests that lower-performing students derive greater benefit from human-AI tutoring than higher-performing students. As such, this study evaluates whether a differentiated tutoring policy can effectively support both groups: human tutors initiate support for lower-performing students, while higher-performing students receive reactive, on-demand support. Using their within-grade median state test scores, we assigned 635 students (grades $5-8$) to receive proactive ($< median$) or reactive ($\geq median$) tutoring. Using a difference-in-discontinuities (DiDC) design, we compare outcomes across two time periods: fall (AI-only tutoring for all) and spring (proactive-reactive human-AI tutoring). This quasi-experimental design isolates the effects of proactive-reactive tutoring approaches by comparing the discontinuity in spring outcomes to the fall baseline, where no such discontinuity existed. Using data around the cutoff (Imbens-Kalyanaraman criterion), we find significant overall improvements from human-AI tutoring compared to AI-only baseline: 25% increase in time on task, 36% in skill proficiency, and 61% in academic growth (standardized MAP test). Between proactive and reactive tutoring, we find comparable improvements in time-on-task and skill proficiency (i.e., no significant difference). We also did not find a significant difference in MAP growth at the cutoff itself, however, proactive tutoring, on average, showed marginally higher MAP growth (75%, $p = .065$) than reactive tutoring, i.e., proactive tutoring was more beneficial to students farther below the cutoff and helped narrow achievement gaps. Our findings provide evidence that differentiated human-AI tutoring addresses the needs of both groups, offering a practical and cost-effective strategy for scaling hybrid instruction.

1. INTRODUCTION

The efficacy of human tutoring is well established in educational research [43], with meta-analyses showing it to be particularly beneficial for lower-performing and socioeconomically disadvantaged students [19, 44]. However, scaling human tutoring remains a persistent challenge due to cost and logistical constraints. Automated alternatives that replicate key elements of human tutoring, such as Intelligent Tutoring Systems (ITS) and Adaptive Tutoring Systems (ATS), have also proven effective [20, 36, 56]. At the same time, Steenbergen-Hu and Cooper's [54] meta-analysis found that automated systems were less effective for lower-performing students than for higher-performing peers, suggesting that some learner needs go beyond the affordances of automated systems (e.g., accountability and motivation).

Recently, hybrid human-AI tutoring models have emerged as a potential cost-effective alternative to high-impact human tutoring [1, 11, 14, 26, 55]. This hybrid approach combines the continuous adaptive support of AI tutors with the supplemental motivational and conceptual support from human tutors [1]. Initial evaluations by Chine et al. [14] reported nearly double the learning gains among students receiving human-AI tutoring compared to a business-as-usual control group. Similar evaluations by Gurung et al. [26] found that human-AI tutoring was more beneficial for lower-performing students than their higher-performing peers, suggesting that the benefits of human support vary by performance level. One possible explanation for this differential benefit is that higher-performing students are better equipped to overcome challenges and utilize the support provided by tutoring systems [36], whereas lower-performing students may benefit from additional motivational or conceptual support beyond the affordances of a tutoring system. Findings from Holstein et al. [31] support this interpretation: strategically directing

teacher time and effort to struggling students increases overall learning gains for the entire group compared to students in a business-as-usual control.

If tutor attention in hybrid settings is especially effective for lower-performing students, then decision policies to optimize tutor time and effort are critical. Yet there is limited evidence on how effective such policies are in real classrooms or what forms they should take (e.g., should tutors proactively initiate support for struggling students or provide reactive, on-demand assistance?). Developing effective policies is particularly important in hybrid settings where a single tutor supports multiple students during a session [14, 26]. Educational data mining is well-positioned to address this gap, as it has demonstrated success with similar decision policies in peer tutoring [59, 58].

In short, there exists a research gap in studying and evaluating effective and adaptive forms of tutor-student pairing in hybrid tutoring. We address this gap by examining a proactive-reactive tutoring policy in which tutors initiate support for lower-performing students, while higher-performing students work independently and receive reactive, on-demand support. To evaluate the policy's effects on learning, we implement a Difference-in-Discontinuities design (DiDC [46]) using prior-year state test performance as the running variable.

2. BACKGROUND

This section reviews the current evidence on the effectiveness of human tutoring, AI tutors, and human-AI tutoring. We also examine how researchers and practitioners have sought to scale these interventions.

2.1 Human Tutoring

Bloom's seminal 2-sigma effect [9] highlighted the impressive learning benefits of one-on-one human tutoring (under ideal conditions) compared to traditional classroom instruction. While such strong gains remain difficult to replicate in real-world settings, efforts to implement human tutoring at scale have consistently shown positive results. For instance, several meta-analyses have reported an effect size of 0.36 SD for human tutoring [19, 44], with Nickow et al. [44] finding tutoring most effective when delivered by certified teachers (0.59 SD). Encouragingly, support from non-professional tutors also resulted in meaningful learning gains (0.21 SD).

The benefits of human tutoring are generally attributed to the personalized motivational and conceptual support provided by tutors [19, 44, 56, 9, 28]. VanLehn's meta-analysis (see [56]) provides a comprehensive review of human tutoring. He attributes tutor success to their ability to closely monitor learning processes, identify misunderstandings, and offer immediate feedback and scaffolding support. Immediate feedback helps tutors address uncertainty in student responses, correct errors, and provide clarification [23, 22]. Scaffolding, in turn, enables tutors to deliver structured support that strengthens reasoning and helps learners grasp complex concepts [17, 13]. Together, these strategies create a highly personalized learning experience tailored to the student's task-specific needs.

2.2 AI Tutors

Current human-AI tutoring research refers to automated tutoring systems as AI tutors [26, 55] to highlight their AI use while contrasting them with their human counterparts. For instance, platforms such as MATHia (formerly Cognitive Tutor [5]) and Lynnette [57] incorporate Symbolic AI and Bayesian Knowledge Tracing (BKT [16]) to estimate student mastery and personalize their math practice. Others, such as W-Pal [50] and ASSISTments [30], utilize natural language processing (NLP) to automate the grading and feedback generation processes. W-Pal uses NLP to help students improve their writing skills (essays), while ASSISTments uses NLP to recommend grades and provide feedback to student work (open-ended problems).

Relatively larger commercial platforms such as IXL [15], i-Ready [25], and ALEKS [21] also leverage AI and psychometric methods to deliver personalized, adaptive support. For example, ALEKS utilizes Knowledge Space Theory [18] to assess student ability and personalize their math practice. IXL, on the other hand, uses learning analytics methods and dashboards to provide insights into student progress [26].

Similar to human tutoring, the effectiveness of AI tutors (particularly, ITS) is well established, with several meta-analyses reporting on their effectiveness [20, 36, 56]. AI tutors have been effectively deployed across a diverse range of educational domains, including mathematics [5, 57], physics [35, 53], writing [40, 50], and programming [41, 47]. Beyond meta-analyses and randomized studies, the effectiveness of AI tutors has also been established through external evaluations. For instance, the Center for Research and Reform in Education (CRRE[1]) has certified platforms such as MATHia, ASSISTments, and IXL as demonstrating strong evidence of improving learning outcomes.

2.3 Human-AI tutoring

During human-AI tutoring, students work independently with AI tutors, while human tutors monitor progress in real time and provide appropriate support [56]. Broadly, these supports are either instructional or motivational. Instructional support addresses gaps in knowledge or misconceptions, typically through hints, explanations, or scaffolding. For example, if a student applies the formula for volume incorrectly, the tutor might ask, "When calculating the volume of a cylinder, do we use the area or the perimeter of the base?" (procedural error). Similarly, to address motivational needs and encourage productive engagement and effort, tutors may affirm student progress by celebrating patterns of success (e.g., individual or streaks).

The quality of human support can be strengthened through learning analytics and teaching-augmentation tools [4]. By surfacing insights into learner needs, these tools can support instructional judgment and pedagogical decisions. For example, Holstein et al. [31], in a teacher-AI context, demonstrated how teaching augmentation tools can effectively guide teacher attention toward students most in need of support. This targeted redirection of teacher attention led to significant improvements in post-test performance compared to business-as-usual control groups.

[1]List of math interventions with evidence of effectiveness.

2.3.1 In-person and Virtual human-AI tutoring

The human-AI tutoring model has been explored in both in-person and virtual settings [14, 7]. For example, Bhatt et al. [7] explored an in-person human-AI model with a 4:1 student-to-tutor ratio. The tutor provided high-dosage tutoring to 2 of the 4 students on alternative days, while the other 2 worked with an AI tutor. This alternating approach was explored as a more cost-effective alternative (30% cost reduction) to the continuous human tutoring model explored by Guryan et al. [26]. Encouragingly, the benefit of an alternating human-AI tutoring model on state-test performance (0.23 SD) was comparable to the high-dosage human tutoring reported by Guryan et al. (0.26 SD). Both studies were year-long randomized controlled trials that used business-as-usual conditions as the control group.

Other researchers have explored the feasibility of virtual human–AI tutoring with remote human tutors, primarily through small-scale randomized trials [48, 49] and quasi-experimental evaluations [11, 26, 55]. Early evaluations report smaller effect sizes for virtual tutoring (0.05 SD; Ready et al. [48]) compared to in-person models (0.23 SD; Bhatt et al. [7]). However, Ready et al. [48] report high variance in AI tutor use, likely due to reduced accountability and disengagement. Importantly, among students who met the recommended dosage, the effect size was comparable to in-person tutoring (0.26 SD). Provided implementation fidelity, virtual tutoring can be as effective as in-person alternatives. Quasi-experimental evaluations [11, 14, 26, 55] provide converging evidence that human-AI tutoring improves both AI tutor progress and standardized test performance.

2.3.2 Heterogeneous Treatment Effect of human-AI tutoring

In a year-long study comparing virtual human-AI tutoring with AI-only tutoring using propensity score matching, Gurung et al. [26] found that access to human tutors was associated with significant improvement in students' grade-level progress, equivalent to 0.36 grade levels by year's end. While these in-platform gains did not translate to significant aggregate effects on state test performance, lower-performing students showed meaningful improvements: students 1 SD below the mean experienced an additional 0.15 SD gain ($p < .001$) on state tests compared to AI-only tutoring. Gurung et al. also observed lower AI tutor use among lower-performing students than their higher-performing peers. Consistent with Ready et al. [48], these patterns suggest the need for additional accountability support for lower-performing students.

3. PRESENT STUDY

Building on evidence that lower-performing students benefit more from additional human tutor support (Section 2.3.2), we propose a proactive-reactive tutoring policy that matches the intensity of human support to student needs. Human tutors initiate additional motivational and conceptual support to lower-performing students and reactive, on-demand support to higher-performing students. We classify students below the within-grade median as lower-performing and those above the median as higher-performing. This approach maximizes human support for students who need it most while maintaining the autonomy of those who benefit from working independently. Throughout the paper, "proactive" and "reactive" refer to how tutors deliver support, not how students seek it. This needs-based tutoring design motivates the following research questions:

RQ1. What are the benefits of human-AI tutoring compared to AI-only tutoring?

- **1.1** To what extent does access to human-AI tutoring improve students' academic growth on standardized tests?
- **1.2** To what extent does access to human-AI tutoring improve students' engagement (time on task) and performance (skills proficiency) in the AI tutor?

For RQ 1.1 and RQ 1.2, we employ a difference-in-differences (DiD [24]) design. Using an AI-only condition as the baseline, we first estimate the overall benefit of hybrid human-AI tutoring, then separately estimate the average effects of proactive and reactive tutoring.

RQ2. Do all students benefit from a policy to assign proactive tutoring to lower-performing students and reactive tutoring to higher-performing students?

For RQ2, we compare the impact of proactive and reactive tutoring on academic growth by estimating the average treatment effect at the discontinuity and testing whether the relative benefits of proactive-reactive tutoring vary by student performance level.

4. METHOD

We use a DiDC design to estimate the effects of introducing human-AI tutoring (RQ1; DiD) and the causal effects of proactive versus reactive tutoring (RQ2; estimated at the median cutoff).

4.1 Dataset

The dataset includes assignment logs from IXL (AI tutor) and standardized test scores for 635 students in grades 5–8 at a middle school in a Mid-Atlantic U.S. state during the 2024–2025 school year. Of approximately 1,000 eligible students, 635 provided informed consent to participate. The IXL logs capture students' platform use throughout the school year, with each record detailing the practiced skill, time-on-task, and skill proficiency.

Standardized assessments include the prior year's state test (Spring 2024) and Measures of Academic Progress (MAP [29]), administered in fall (Sept 2024), winter (Dec 2024), and spring (Apr 2025). Developed by the Northwest Evaluation Association (NWEA), MAP uses a continuous vertical scale to track academic growth. Of the 635 students, prior-year state test scores were available for 557; the remaining 78 were newly enrolled and lacked prior-year records. Data collection followed IRB protocols, and participation was based on opt-in informed consent.

4.2 Adaptive Tutoring System (IXL)

IXL is an adaptive tutor that dynamically adapts to student performance at two levels: item selection (based on performance within a skill) and skill selection (based on overall skill proficiency). This approach to adaptive support

is characterized by micro-adaptive and macro-adaptive support [52]. Student proficiency is estimated using SmartScore (0—100), IXL's proprietary measure, where scores above 80 indicate proficiency and a score of 100 indicates mastery.

In terms of effectiveness, IXL is classified as a Tier 1 platform[2] ("strong evidence") [15], showing an average effect size of 0.08 SD compared to business-as-usual controls on standardized tests. State-level evaluations comparing IXL and non-IXL schools have replicated these findings with effect sizes of 0.10–0.13 SD [34, 51].

4.3 Virtual Human-AI Tutoring

Remote tutors provided tutoring support via Zoom during math practice on IXL. Tutors were graduate and undergraduate students from a U.S.-based university who received tutor training [37, 38]. Tutoring sessions were conducted twice a week during regular school hours.

At the beginning of each classwork session, students were assigned to individual Zoom breakout rooms by remote tutors, where they independently practiced math on IXL. After setup and wrap-up time, each session typically provided approximately 30 minutes of practice. On average, proactive tutors supported 4 students per session (∼7.5 minutes per student), while 1 tutor provided reactive support to all students in the reactive group (∼ 10 students; ∼1–3 minutes per student). Proactive tutors actively checked in on student progress by visiting breakout rooms, whereas reactive tutors provided on-demand support when students requested help via Zoom chat or the hand-raise feature.

Implementation fidelity was monitored at two levels: session leads monitored protocol adherence and tutoring quality in real time (session leads often served concurrently as reactive tutors), while senior tutor supervisors observed multiple sessions to ensure consistency across tutors.

4.4 Experimental Design

Traditionally, regression discontinuity (RD [33]) designs leverage cutoffs to estimate the causal effects of policies or interventions. Common examples include age thresholds for legal drinking, test-score cutoffs for scholarship eligibility, and income thresholds for access to social programs. These cutoffs are often constrained by exogenous factors such as budgetary constraints or legal precedent, rather than by theoretical or empirical evidence about where the intervention would be most beneficial.

Unlike conventional cutoffs, we use an evidence-based cutoff intended to benefit both proactive and reactive groups. Building on Gurung et al.'s [26] finding that the benefits of human-AI tutoring vary by prior performance (interaction: -0.13 SD, p = 0.03), we chose median prior performance as the cutoff. Given the expected heterogeneous effects, the choice of cutoff requires further elaboration. As illustrated in Figure 1, if the median closely approximates the optimal cutoff, we could observe an equivalence between conditions at the cutoff (i.e., no significant difference) and an interaction indicating students farther below the median experience greater benefits from proactive tutoring (Figure 1 b).

However, equivalence at the cutoff does not, by itself, indicate whether the differentiated policy produced meaningful benefits. Given these considerations, we use MAP growth measures and DiDC design [46] that combines RD [33] with difference-in-differences (DiD)[24]. By leveraging fall baseline outcomes (IXL use and MAP performance), DiDC pro-

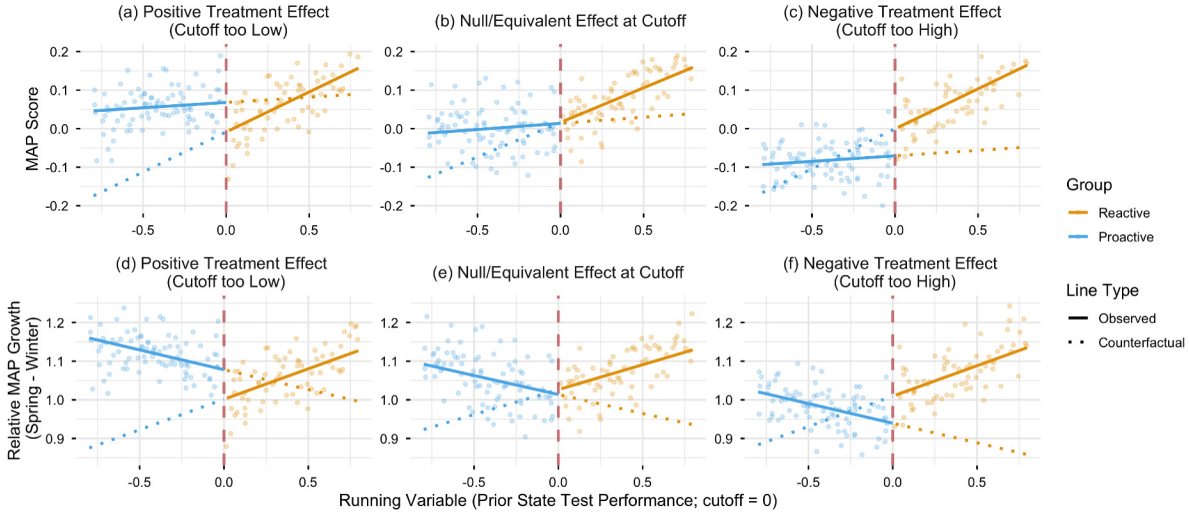

Figure 1: Simulated scenarios for RD (top panel) and DiDC (bottom panel). The top panel shows heterogeneous treatment effects in an RD design, with proactive tutoring assigned below the cutoff and reactive tutoring above it. Depending on cutoff placement, proactive tutoring may appear (a) more beneficial, (b) equivalent, or (c) less beneficial than reactive tutoring at the cutoff, with effects varying by prior performance. The bottom panel shows the corresponding DiDC estimates using the MAP growth ratio (observed vs. expected) between periods: (d) positive growth ratio when the cutoff is too low, (e) null growth ratio when it closely approximates the optimal cutoff, and (f) negative growth ratio when it is too high.

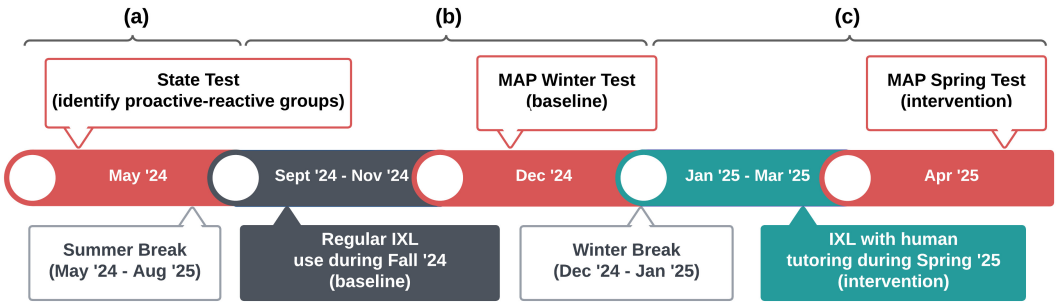

Figure 2: Experimental timeline for evaluating a proactive-reactive tutoring policy. Fall IXL data and winter MAP scores serve as the baseline, while the spring IXL data and spring MAP scores capture the effect of the intervention.

vides two complementary estimates: First, a DiD analysis compares spring human-AI tutoring to the fall AI-only baseline, establishing whether hybrid tutoring improved outcomes overall. Second, the DiDC estimator isolates the causal effect of proactive versus reactive tutoring at the cutoff by differencing out any baseline discontinuity. Figure 1 (d—f) illustrates how gains in MAP scores from winter to spring are used to estimate the impact of introducing human-AI tutoring in the spring.

4.4.1 *Experiment Timeline*

Figure 2 illustrates the experimental timeline. Students were assigned to proactive or reactive tutoring using a within-grade median cutoff in prior-year state test scores (Figure 2a). By introducing human tutoring in the spring (Figure 2 c), we can use the Fall IXL measures and winter MAP scores as pre-intervention baselines (Figure 2 b).

For RQ1, we use a within-subjects DiD [24] comparison between the baseline and intervention periods to estimate the overall and the differential benefits of proactive and reactive tutoring. We use Imbens and Kalyanaraman (IK) bandwidth [32] near the cutoff to strengthen the parallel time trends assumption by restricting the analysis to locally comparable students, making it plausible that their growth trajectories would have been similar absent the introduction of human-AI tutoring.

For RQ2, we use DiDC to estimate the treatment effect at the cutoff and examine variation in the benefits of proactive versus reactive tutoring across student performance levels, measured by MAP gain (winter to spring). By differencing out the fall baseline discontinuity, DiDC isolates the causal effect of the differentiated policy on spring academic growth.

4.5 Analysis Plan

To address our research questions, we first discuss MAP growth norms and the local comparability assumption required for RD design. We then discuss our analysis plan to examine the impact of the human-AI tutoring policy on student IXL use and MAP performance (RQ1 and RQ2). All analyses are conducted in R using *lme4*, *rdd*, and *lavaan*.

4.5.1 *Expected MAP Growth*

The MAP [29] assessment reports scores on a continuous vertical scale designed to measure academic growth over time in Rasch Units (RIT). The vertical scale allows comparisons both within and across school years. To contextualize observed gains, we use NWEA's expected growth norms, which summarize typical score changes between consecutive test administrations for the national MAP testing population. The expected growth norms presented in Table 1 are from the NWEA 2025 release (based on 13.8 million students).[3]

Table 1: NWEA 2025 expected MAP growth norms by grade. The higher fall-to-winter growth also reflects the longer interval between fall and winter ($\sim$ 3 months) than between winter and spring ($\sim$ 2 months), as spring MAP tests are generally administered early in April.

	Expected MAP Growth (RIT)	
Grade	Fall to Winter	Winter to Spring
5	6	4
6	6	4
7	4	3
8	4	3

To account for grade-level differences in typical MAP growth between consecutive test administrations, we normalize each student's observed winter to spring MAP gain by the expected gain for their grade using Equation 1. For example, a 4-point increase from winter to spring corresponds to 100% of expected growth for grades 5 and 6, but 133% of expected growth (i.e., 33% above expected) for grades 7 and 8.

$$\text{Relative MAP Growth} = \frac{\text{Observed Growth}}{\text{Expected Growth}} \quad (1)$$

4.5.2 *Bandwidths and Local Comparison*

We use the IK bandwidth selector [32] to support credible estimation of treatment effect at the cutoff. IK bandwidth helps identify the analytic sample around the cutoff that minimizes mean squared error for a local linear RD estimate. Limiting comparisons to the local neighborhood strengthens the credibility of the continuity assumption by enhancing comparability across observed characteristics and reducing differences in unobserved determinants of outcomes. The IK procedure balances the bias–variance tradeoff inherent in

[3]NWEA 2025 Norms Quick Reference (resource page)

RD designs: narrower windows reduce bias from functional-form misspecification and distant comparisons, while wider windows improve precision.

4.5.3 RQ1: Effects of Introducing Human Tutors

Impact of Human-AI tutoring on Academic Growth (RQ1.1). We estimate the effect of introducing human-AI tutoring using a within-subject comparison of the students' relative MAP growth from winter to spring (human-AI tutoring) with fall to winter (AI-only baseline). We use a multilevel mixed-effects model with random effects for grade and student within grades, and period indicators (AI-only tutoring, human-AI tutoring), as outlined in Equation 2.

$$\mathrm{Y}_i = \beta_0 + \beta_1 \,\text{human-AI tutoring}_{ig} + u_{ig} + v_g + \varepsilon, \quad (2)$$

Here, β_1 estimates the added benefit of human-AI tutoring on relative MAP growth compared to the AI-only tutoring, and β_0 represents the expected outcome under AI-only tutoring. We account for between-grade variance using random intercepts v_g, between-student variance within grades using random intercept u_{ig} and assume normality for $v_g \sim \mathcal{N}(0, \sigma_v^2)$, $u_{ig} \sim \mathcal{N}(0, \sigma_u^2)$ and $\varepsilon_i \sim \mathcal{N}(0, \sigma^2)$, with v_g and u_{ig} independent of ε_i (and of each other).

We extend Equation 2 to evaluate the difference in outcomes between proactive and reactive tutoring, as outlined in Equation 3.

$$\begin{aligned}\mathrm{Y}_i = \beta_0 &+ \beta_1 \,\text{human-AI tutoring}_{ig} + \beta_2 \,\text{proactive}_{ig} \\ &+ \beta_3 \,\text{human-AI tutoring}_{ig} \times \text{proactive}_{ig} \\ &+ u_{ig} + v_g + \varepsilon,\end{aligned} \quad (3)$$

Here, β_2 estimates the baseline difference between groups in the fall (AI-only), whereas β_3 estimates the additional benefit of access to proactive human-AI tutoring.

Impact of Human-AI tutoring on IXL Engagement and Performance (RQ1.2). Beyond MAP performance, we also estimate the effect of introducing human-AI tutoring on IXL engagement (time-on-task) and performance (skill proficiency). We limit the analysis to the 10 normal school weeks preceding each MAP test, as the fall semester was longer than the spring (the spring MAP was administered early in April). We use the same model specification outlined in Equations 2 and 3 to estimate the overall impact of human-AI tutoring and compare the benefits of proactive and reactive tutoring on student engagement and performance.

4.5.4 RQ2: Do All Students Benefit From the Differentiated Tutoring Policy

We use DiDC to estimate the treatment effects of proactive and reactive tutoring at the cutoff and to examine treatment-effect heterogeneity across performance levels.

$$\begin{aligned}\mathrm{Y}_{ig} = \beta_0 &+ \beta_1 \,\text{Proactive}_{ig} + \beta_2 \,\text{PriorPerformance}_{ig} \\ &+ \beta_3 \left(\text{Proactive}_{ig} \times \text{PriorPerformance}_{ig}\right) \\ &+ v_g + \varepsilon,\end{aligned} \quad (4)$$

Here, Y_{ig} is the relative MAP growth (Equation 1) from winter to spring for student i in grade g. β_1 estimates the relative MAP growth of receiving proactive versus reactive tutoring at the cutoff, β_2 estimates the association between prior performance and relative MAP growth, and β_3 estimates the heterogeneity in the treatment effect of proactive tutoring with prior performance. We include a grade-level random intercept v_g to account for between-grade variability, assuming $v_g \sim \mathcal{N}(0, \sigma_v^2)$ and $\varepsilon_{ig} \sim \mathcal{N}(0, \sigma^2)$, with v_g independent of ε_{ig}.

5. RESULTS

The code used for the analysis is available in the anonymous GitHub repository[4].

5.1 Descriptive Statistics

The descriptive statistics for student performance are reported in Table 2. These include prior year's state test scores and the winter and spring MAP results.

Table 2: The mean and SD of student performance on the state and MAP tests.

Grade	N	State Test	Winter MAP	Spring MAP
5	167	1046 (108)	218 (13)	231 (14)
6	154	1014 (110)	226 (17)	229 (17)
7	114	984 (148)	229 (18)	232 (18)
8	122	955 (110)	231 (18)	238 (18)

5.2 Validity Tests and Bandwidth Selection

To ensure validity, we first conducted a McCrary manipulation test [39] to assess whether the running variable (state test scores) exhibited strategic sorting around the cutoff. We found no statistically significant density discontinuities at the cutoff across all four grades (all $p > .05$), providing no evidence of manipulation. We then used the IK bandwidth procedure [32] to identify the optimal range around the cutoff for credible estimation of the treatment effect at the cutoff.Table 3 reports the optimal bandwidth ranges for each grade, estimated using the running variable (prior state test performance) and winter-to-spring MAP gains. Finally, we evaluated the local comparability assumption by assessing covariate balance (ethnicity, gender, socioeconomic status) and checking continuity in baseline measures (winter MAP, fall IXL time on task, and fall IXL skill proficiency) within the selected bandwidths. Overall, the diagnostics are consistent with the assumptions required for the DiDC design.

5.3 RQ1: Human-AI vs. AI-only Tutoring

We estimate the benefit of human-AI tutoring by comparing spring MAP test performance, IXL time on task, and skill proficiency to the AI-only baseline period. We first estimate the overall effect using a within-subject comparison between

[4]http://tiny.cc/EDM26

Table 3: Sample sizes determined using the IK bandwidth selection procedure [32], with bandwidth estimated in SD.

Grade	IK Bandwidth	n	Human-AI Tutoring	
			proactive	reactive
5	0.77	78	36	42
6	0.71	75	39	36
7	0.71	57	32	25
8	0.89	77	38	39
	Total:	287 (52% of N)		

human-AI tutoring and AI-only baseline (Equation 2). We then use a DiD approach (Equation 3) to compare the differential effects of proactive and reactive tutoring. We report results for both the full sample and the subsample within the IK bandwidth. Given that the parallel trends assumption required for DiD analysis is more plausible within the IK bandwidth due to greater local comparability, we prioritize these estimates for causal interpretation.

5.3.1 *RQ1.1: Human-AI Tutoring and Academic Growth*

We fit multilevel regression models (Equation 2) with both the IK bandwidth subsample and the full sample. Student-level random intercepts produced singular fits (i.e., student-level variance estimated at 0) and were omitted. The final models include grade-level random effects and a fixed effect for human-AI tutoring (with AI-only tutoring as reference).

As illustrated in Figure 3, within the IK bandwidth, human-AI tutoring was associated with significant improvements in relative MAP growth by an additional 61% (p = .003). The full sample showed a similar but not significant trend of 26% improvement (p = .086). Additionally, both models had an interclass correlation between 0.03–0.04, indicating that only 3–4% of the variance is attributable to grade-level differences, i.e., the intervention's effect was consistent across grades.

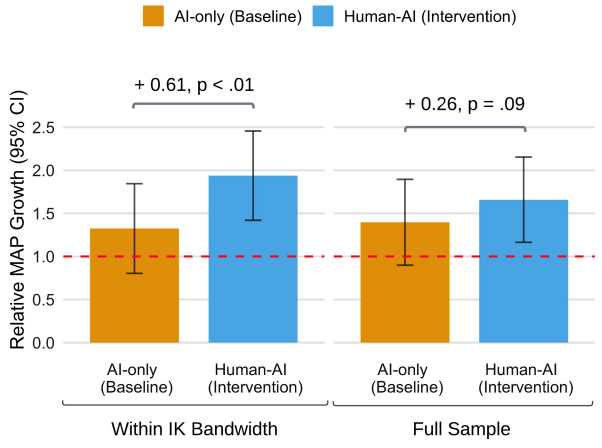

Figure 3: Within-subject improvement of relative academic gain from the introduction of human-AI tutoring. The dotted red line represents students meeting 100% of their expected growth norm on the MAP assessment.

Table 4 compares relative MAP growth between proactive and reactive tutoring groups (Equation 3), using AI-only tutoring as the baseline. Within the IK bandwidth subsample, proactive tutoring produced larger relative growth than reactive tutoring (0.75, p = .065), with proactive students achieving 2.18× expected growth compared to 1.70× for reactive students in the spring. A similar pattern was observed in the full sample, where the proactive tutoring produced larger relative growth (0.78, p = .010) than reactive tutoring.

Table 4: Comparing the relative growth between the proactive and reactive tutoring from human-AI tutoring compared to AI-only baselines.

	IK Bandwidth	Full Sample
	β	β
(Intercept)	1.46 ***	1.66 ***
Human-AI	0.24	-0.12
proactive	-0.27	-0.53 *
Human-AI×proactive	0.75$^{\bullet}$	0.78 *
ICC	0.03	0.04
N_{grade}	4	4

$^{\bullet}p < 0.1$, $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$

Overall, human-AI tutoring was associated with improved relative academic growth for both proactive and reactive groups (Figure 3), with the proactively tutored students experiencing larger relative growth than their reactively tutored peers (Table 4).

5.3.2 *RQ1.2: Human-AI Tutoring and IXL Use*

Impact of human-AI tutoring on IXL engagement: As illustrated in Figure 4, we find that human-AI tutoring associated with significant improvement in student time on task in both the IK bandwidth subsample (25%; +1.32 hours, p < .001) and the full sample (31%; +1.61 hours, p < .001). The models had an intraclass correlation between 0.51–0.58, reflecting strong student-level variation in engagement within grades.

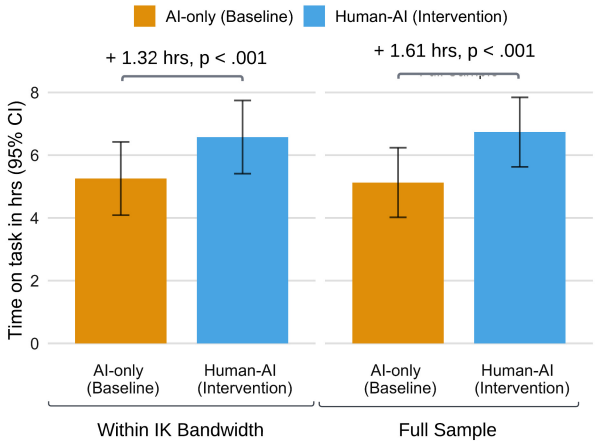

Figure 4: Within subject improvement of time on task in IXL from the introduction of human-AI tutoring.

Additional analysis revealed a significant increase in student

time on task from human-AI tutoring compared to AI-only tutoring (Table 5). However, we did not find a significant difference in time on task between proactive and reactive tutoring in either the IK bandwidth subsample or the full sample, i.e., time on task did not differ reliably between the two tutoring approaches.

Table 5: Comparing the impact of proactive and reactive human-AI tutoring on student engagement in IXL.

	IK Bandwidth	Full Sample
	β	β
(Intercept)	5.40 ***	5.37 ***
Human-AI	1.38 ***	1.68 ***
proactive	-0.29	-0.51$^{\bullet}$
Human-AI×proactive	-0.11	-0.14
ICC	0.51	0.57
$N_{student:grade}$	287	491
N_{grade}	4	4
$R^2/adj.R^2$	0.041/0.527	0.063/0.599

$^{\bullet}p < 0.1$, $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$

Impact of human-AI tutoring on IXL performance: As illustrated in Figure 5, we find that human-AI tutoring was associated with significant improvement in student skill proficiency in both the IK bandwidth subsample (36%; +6.10 skills, p < .001) and the full sample (42%; +6.75 skills, p < .001). The models had an intraclass correlation between 0.52–0.60, reflecting strong student-level variation in engagement within grades.

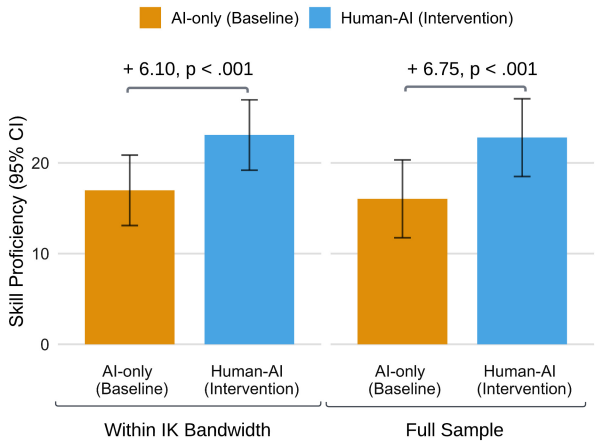

Figure 5: Within subject improvement of skill proficiency in IXL from the introduction of human-AI tutoring.

Further analysis revealed a significant increase in skill proficiency from human-AI tutoring for both groups compared to the AI-only tutoring (Table 6). The benefit was significant for both the IK bandwidth subsample (6.87, p<.001) and the full sample (7.97, p<.001). Within the IK bandwidth, results suggest that the proactive group, on average, had lower skill proficiency than the reactive group (-2.17, p=.067). Following the introduction of human support, despite improvements for both groups, the proficiency gap widened by 3.69 skills (14.79%), with the reactive group demonstrating greater proficiency than their proactive peers.

Table 6: Comparing the impact of proactive and reactive human-AI tutoring on student skill proficiency in IXL.

	IK Bandwidth	Full Sample
	β	β
(Intercept)	18.08 ***	17.49 ***
Human-AI	6.87 ***	7.97 ***
proactive	-2.17$^{\bullet}$	-3.06 **
Human-AI×proactive	-1.52	-2.56**
ICC	0.51	0.59
$N_{student:grade}$	287	491
N_{grade}	4	4
$R^2/adj.R^2$	0.094/0.554	0.115/0.634

$^{\bullet}p < 0.1$, $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$

In IXL, both proactive and reactive groups were associated with significant improvement in their time on task and skill proficiency from human-AI tutoring compared to the AI-only baseline. While there was no significant difference in time on task between the two groups, we find suggestive evidence that the reactively tutored students demonstrated higher skill proficiency than their proactively tutored peers.

5.4 RQ2: Proactive vs. Reactive Tutoring

Building on RQ1, we estimate the differential effect of proactive versus reactive tutoring at the discontinuity using (Equation 4). Student prior performance is standardized within grades and adjusted to have the cutoff (median) be 0 for each grade. Under the local comparability assumption, we use the IK bandwidth subsample to estimate the treatment effect at the cutoff. To assess the robustness of our findings, we conducted several additional analyses: sensitivity analyses using alternative bandwidth selections, robust bias-corrected estimates using CCT bandwidth [12], and donut checks excluding observations immediately adjacent to the cutoff. The results of the additional analysis are available in the linked anonymous GitHub repository[5].

Figure 6 illustrates the differential effects of proactive and reactive tutoring across prior performance. At the cutoff, students in the reactive group achieved 1.74× expected MAP growth (+74%, p = .007). Although proactive students at the cutoff showed numerically lower growth, this difference was not statistically significant (-0.33, p = .579). The interaction between proactive tutoring and prior performance was also not statistically significant (-1.61, p = .247); however, the magnitude of this estimate suggests a meaningful pattern. This point estimate indicates that for each SD below the cutoff, the benefit of proactive tutoring increased by approximately 1.6×—a magnitude nearly equal to the baseline effect at the cutoff (1.74×). This suggests that the higher overall relative MAP gains for the proactive group (RQ1) compared to reactive tutoring are driven by greater benefits among students farther below the cutoff.

6. DISCUSSION

Given the heterogeneous treatment effects of human-AI tutoring, we study a differentiated proactive–reactive tutoring policy in which lower-performing students receive tutor-initiated support, whereas higher-performing students re-

[5]http://tiny.cc/EDM26

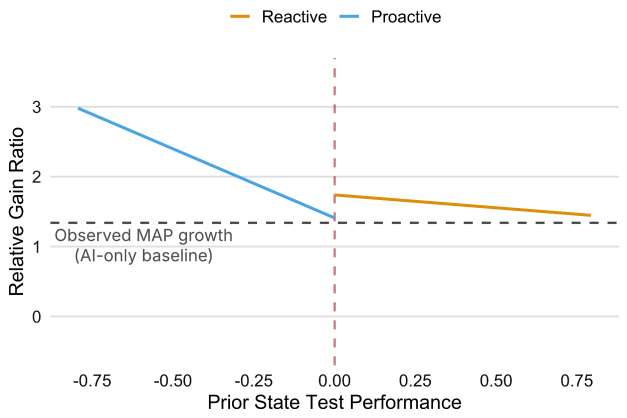

Figure 6: Examining the impact of proactive and reactive tutoring on students' relative MAP growth. The gray line represents the students' relative MAP growth (1.3 ×) during the AI-only baseline period. Additionally, Relative Gain

ceive reactive, on-demand support. Using a quasi-experimental DiDC design, we show that this policy improves engagement and overall learning while delivering larger gains for lower-performing students, offering a practical and scalable strategy for human–AI tutoring. As we discuss these findings, it is important to note that the estimates likely reflect the benefits of the implemented policy as a bundle, rather than the isolated effect of the assignment policy itself. As with most real-wold interventions, the observed gains likely encapsulate the combined effects of student needs, teacher context, tutor behavior, AI tutor use, and the proactive–reactive assignment rule. Next, we review the findings and their broader implications for educational research and policy.

6.1 Evaluating the Impact of Human-AI Tutoring on Standardized Test Performance

We find that access to human-AI tutoring significantly improved student performance on standardized tests (Figure 3), compared to AI-only tutoring. Within the IK bandwidth, we observe an average increase of 61% in MAP performance. Overall, students receiving human-AI tutoring demonstrated 2× the expected MAP growth during this period. While access to human-AI tutoring was beneficial to both groups, we find that it was particularly beneficial for the proactively tutored students, with the students experiencing an additional 75% improvement in performance—proactive tutoring helped narrow the achievement gap between the lower and higher performing students.

Our findings that students achieved approximately 2 × the expected national NWEA growth norms align with findings from Chine et al. [14]. As the Chine et al. study was conducted using in-person human-AI tutoring, it is promising that we are observing similar results with remote human tutors. Additionally, a key methodological distinction is that Chine et al. used a propensity-matched control group, whereas we compare against expected norms from the national sample of all MAP assessment takers.

6.2 Evaluating the Impact of Human-AI Tutoring on AI tutor use

Our evaluation of human-AI tutoring on student engagement and proficiency in IXL was consistent with the impact on MAP scores. Within the IK bandwidth, access to human-AI tutoring increased student time on task by 25% and skill proficiency by 36% across both groups. Notably, both groups achieved similar gains through different support mechanisms. Proactive tutoring helped lower-performing students sustain engagement beyond what AI-only support could provide, whereas reactive tutoring allowed higher-performing students to work independently at their own pace while retaining access to additional human support. Together, these results suggest that aligning tutoring intensity with student needs benefits both groups.

Our findings on the benefits of human-AI tutoring on IXL measures are consistent with recent findings from Borchers et al. [11], who observed increases of 25% in student time on task and 38% in skill proficiency with access to human-AI tutoring. An important distinction is that Borchers et al. used an additional rewards-based goal-setting intervention to motivate IXL use, whereas we explored the impacts of a differentiated tutoring policy that allocates tutor time and attention based on prior performance. These complementary approaches suggest promising potential for combining differentiated tutoring with goal-setting interventions to further improve the effectiveness of human-AI tutoring.

6.3 Comparing Proactive and Reactive Human-AI Tutoring

We find no significant difference between proactive and reactive tutoring at the cutoff. Given that human-AI tutoring overall improved student MAP performance by 61% and that proactive tutoring produced 75% greater gains than reactive tutoring on average, this null result at the cutoff suggests that the median represents an appropriate threshold where both groups benefit from differentiated support. However, as illustrated in Figure 6, the benefits of proactive tutoring were larger for students farther below the median, indicating that the observed improvements in MAP performance are driven by improvement in MAP performance of lower-performing students and thus contribute to the narrowing of achievement gaps.

6.4 Tutoring and EDM

Tutoring has long been a core focus of EDM, and research on effective human tutoring has shaped the design of tutoring systems [13, 56]. Over time, these systems have scaled access to tutoring support [5, 30, 3]. While AI tutors can provide reliable, continuous support at scale, they often fall short in delivering the motivational and conceptual support that human tutors excel at, particularly when student needs extend beyond current AI capabilities [54, 1]. Recent work on human-AI tutoring explores how targeted human support can complement AI tutors [48, 26, 14]. Our study advances this line of research by providing empirical evidence supporting the learning benefits of a differentiated tutoring strategy based on student needs and readiness. Beyond demonstrating the benefits of human-AI tutoring, these findings highlight opportunities to draw on established EDM methods for optimizing support allocation [59, 58], learner modeling

for adaptive interventions [2], and behavioral analytics that detect and respond to engagement states in real time [6, 27].

Taken together, our findings provide converging evidence with prior human-AI tutoring research. We find that our differentiated policy using remote tutors can achieve learning gains comparable to in-person human-AI tutoring [14]. Our approach also extends prior work on AI tutor engagement by achieving engagement and learning outcomes comparable to those reported by Borchers et al. [11], which used reward-based goal-setting interventions. These results underscore the value of adaptive support tailored to student needs and readiness over a one-size-fits-all approach.

7. LIMITATIONS

Our quasi-experimental DiDC design [46] provides evidence for the benefits of personalizing tutoring support, though stronger causal evidence could be achieved from randomized controlled trials. Similarly, our reliance on national growth norms as a reference point, rather than a matched control group, limits causal inference. However, ethical considerations complicate randomizing students to different support conditions within the intervention, given our findings that proactive support substantially benefits lower-performing students. A more appropriate RCT design would be to compare the differentiated human-AI tutoring policy as a whole with a business-as-usual control condition, providing a more rigorous baseline for evaluating intervention effects.

It is also important to acknowledge the limitations of our dichotomous allocation of support. Dividing students into proactive and reactive groups at the median may oversimplify the relationship between student need and optimal tutoring intensity. For instance, students much farther below the median (the bottom 10%) may require more intensive support than the proactive tutoring used in our study (1 tutor for 4 students). Additionally, our treatment allocation relied on a single baseline performance measure, leading to a static allocation of students to groups, whereas dynamically determining student need based on ongoing performance and engagement could further enhance the benefits of differentiated support. Past EDM research has developed algorithms for dynamic pairing policies in peer tutoring, which future work could repurpose for the study of optimal tutor-to-student pairing policies [59].

8. FUTURE WORK

The absence of Zoom interaction data (actual student–tutor interactions) represents a missed opportunity for deeper analysis, especially for understanding which elements of proactive tutoring were effective for student learning. We primarily relied on lead tutors and tutor supervisors to ensure implementation fidelity; better Zoom integration would provide additional data to monitor program implementation and identify areas for improvement. For instance, Borchers et al. [10] found that brief tutor visits during a remote tutoring session can significantly improve student performance. These analyses could better explain the success of our intervention. Access to multi-modal Zoom sessions data could provide a more comprehensive view of the dynamics of human-AI tutoring, presenting opportunities to build on current research [13, 23, 22, 17]. These insights would also enhance our understanding of how differentiated support models function in practice and inform their ongoing refinement.

An important improvement for future implementations is to facilitate consistent student–tutor pairing to support relationship building [45, 42]. In our study, students were randomly assigned to Zoom breakout rooms at the start of each session, and tutors were allocated a fixed set of rooms (e.g., a tutor might oversee rooms 1–4, though the students in those rooms varied across sessions). While this approach simplified logistical constraints, it limited opportunities for relationship-building and continuity of support across sessions. Prior work underscores the value of such consistency: Bleiberg et al. [8] found that female students experienced greater benefits when paired with female tutors, highlighting how relational dynamics and familiarity can enhance tutoring effectiveness. Related analyses of the differential impact of tutoring across student demographic groups could be subject to future work.

9. CONCLUSION

This study explored a key challenge in scaling human-AI tutoring: how to allocate limited human tutor support to effectively meet diverse student learning needs. Motivated by preliminary evidence that lower-performing students derive greater benefits from human-AI tutoring than higher-performing peers, we evaluated a differentiated proactive-reactive tutoring policy. Results from our quasi-experimental study provide evidence of a differentiated policy benefiting both lower-performing and higher-performing students. Compared to AI-only baselines, human-AI tutoring significantly improved students' time on task (+25%) and skill proficiency (+36%) in IXL, as well as their relative academic growth (+61%) on standardized MAP tests. Notably, the differentiated policy helped narrow achievement gaps, with lower-performing students experiencing 75% greater improvement in academic growth from proactive support compared to reactive tutoring. Relative to expected norms from the national sample of all MAP assessment takers, differentiated human-AI tutoring resulted in students achieving approximately 2× the expected growth. These findings provide converging evidence with ongoing evaluations of human-AI tutoring, demonstrating that differentiated allocation policies can significantly improve both learning outcomes and student engagement while optimizing limited human tutor resources.

These findings have important implications for scaling personalized learning and for EDM research. By differentiating support according to student needs (1:4 tutor-to-student ratio for proactive tutoring, 1:10 for reactive), human-AI tutoring can balance effectiveness with resource constraints. Students requiring greater assistance benefit from proactive support, while those demonstrating readiness for independent work benefit from reactive, on-demand support. This work demonstrates how readily available performance data can inform resource allocation decisions. Future EDM research could enhance this approach through more sophisticated learner modeling to dynamically adjust support allocation, behavioral indicators to identify when students need intervention, and adaptive algorithms that refine allo-

cation thresholds based on ongoing performance. This differentiated approach offers a sustainable pathway for scaling human-AI tutoring while advancing EDM's capacity to close the loop between learner diagnosis and instructional action.

ABSTRACT

Large Language Models (LLMs) are increasingly deployed to automatically label and analyze educational dialogue at scale, yet current pipelines lack reliable ways to detect when the models are wrong. We investigate whether reasoning generated by LLMs can be used to predict the correctness of a model's own predictions. We analyzed 30,300 teacher utterances from classroom dialogue, each labeled by multiple state-of-the-art LLMs with an instructional move construct and an accompanying reasoning. Using human-verified ground-truth labels, we framed the task as predicting whether a model's assigned label for a given utterance was correct. We encoded the LLM reasoning using Term Frequency-Inverse Document Frequency (TF-IDF) and evaluated five supervised classifiers on their ability to predict label correctness. Among the evaluated classifiers, Random Forest achieved the strongest performance with an F1 score of 0.83 (Recall = 0.854), successfully identifying the majority of incorrect predictions and significantly outperforming baselines. Training specialist detectors for specific instructional move constructs further improved performance on difficult constructs, suggesting that error detection benefits from construct-specific linguistic cues. Using the Linguistic Inquiry and Word Count (LIWC) framework, we examined four linguistic constructs as markers of correctness: Causation (logical reasoning), Differentiation (complexity), Tentativeness (uncertainty), and Insight (metacognition). Correct predictions were characterized by grounded causal logic (e.g., 'because', 'therefore'), while faulty reasoning was five times more likely to rely on epistemic hedging (e.g., 'might', 'could') and twice as likely to employ performative metacognition (e.g., 'think', 'realize'). Syntactic complexity did not distinguish correct from incorrect reasoning, indicating that evidential grounding — not structural sophistication — drives validity. Our findings also challenge the "longer reasoning is better" heuristic; for most constructs, concise reasoning is a stronger predictor of correctness. These findings suggest that reasoning-based error detection provides a practical and scalable approach to quality control in automated educational dialogue analysis.

Large Language Models, Natural Language Processing, Automated Coding, Classroom Discourse

1. INTRODUCTION

The analysis of qualitative educational data is increasingly central to Educational Data Mining (EDM) and related fields [11, 46]. Researchers routinely annotate discussion posts, assignments, or dialogue with specific constructs to support downstream analyses, such as Epistemic Network Analysis (ENA) [4] or sequential pattern mining [39]. These annotations enable large-scale investigations of how students and educators engage in learning tasks in classrooms [29], tutoring sessions [8], and online chat environments. Historically, this work has relied on supervised classification methods [5, 9], and more recently, Large Language Models (LLMs) to annotate data at scale [45, 21]. However, automated annotation pipelines often exhibit low to moderate reliability and inconsistent generalization across constructs [24, 18]. In particular, false positives remain a persistent challenge because they can systematically bias downstream structural and sequential modeling [40].

This paper addresses this central reliability gap: current pipelines lack robust mechanisms for detecting when automated annotations are wrong. Existing work primarily focuses on improving model accuracy, yet even high-performing models produce errors that propagate into subsequent analyses. We propose a complementary approach: using the reasoning generated by LLMs as a diagnostic signal for identifying misclassifications. Rather than treating LLMs as black-box classifiers, we examine whether their reasoning can serve as a secondary layer of quality control.

We operationalize this idea by training models to predict whether an LLM-generated annotation is correct or a false positive based solely on the accompanying reasoning text– asking the LLM to provide reasoning along with the annotation. Using traditional natural language processing (NLP) and machine learning (ML) methods, we show that correct and incorrect annotations can be distinguished with high accuracy ($F_1 = 0.830$ to 0.854), with further improvements when models are trained for specific instructional constructs

(e.g., separate models for classifying "Press for Accuracy" and "Press for Reasoning"). We additionally analyze linguistic markers associated with misclassification, finding that reasoning supporting false positives is longer and contains substantially more epistemic hedging, suggesting that models often verbalize their own uncertainty. Together, these findings introduce reasoning-based error detection as a scalable strategy for improving the robustness of automated discourse analysis in education.

This paper makes three main contributions: First, we introduce reasoning-based error detection as a new reliability layer for automated educational discourse annotation. Second, we demonstrate that traditional NLP and ML methods can accurately predict LLM annotation misclassification using only the LLM reasoning. And third, we identify linguistic markers of correctness and error in LLM reasoning, providing new insight into how and when automated annotations fail.

2. RELATED WORK

2.1 The Shift to Large Language Models in Classification

The EDM community has a long history of using machine learning and AI methods for classifying complex data at scale, ranging from students' knowledge states [7, 30] to epistemic affect [10, 27]. While much of this classification has dealt with structured log-file data using supervised machine learning models, recent work has shifted towards classification using Large Language Models (LLMs). This shift has been particularly beneficial for processing unstructured data, such as open-ended math problems [31], dialogues in tutoring sessions [1, 47], classroom discourse [37, 43], and writing tasks [26, 13].

Unlike many classification methods that require extensive feature engineering or large labeled datasets, LLMs offer the potential for "zero-shot" or "few-shot" classification, allowing researchers to scale qualitative coding to datasets previously considered too costly to annotate manually [18, 12, 49]. To improve classification accuracy, researchers have employed a variety of methods beyond simple prompting. For instance, recent studies have demonstrated that including diverse few-shot examples significantly boosts performance in identifying collaborative argumentation moves [36] and assessing instructional quality [29]. Furthermore, the integration of reasoning—asking the model to "think" before it classifies—has been shown to improve the detection of latent constructs like self-regulated learning processes [47]. By explicitly modeling the inference steps, these methods aim to bridge the gap between surface-level keywords and the deep semantic understanding required for qualitative coding.

2.2 Challenges with Misclassifications, Faithfulness

Despite these methodological advances, the reliability of LLM-based annotation remains inconsistent. While some studies report high agreement between LLMs and human experts for broad categories [26], others highlight significant declines in performance when models encounter ambiguous or high-inference constructs [18]. Crucially, [24] found that LLM precision in deductive coding tasks can vary drastically (from 0.10 to 0.87) depending on the specific prompt and construct. Similarly, [40] observed that LLMs consistently exhibit a high false positive rate, even when achieving moderate reliability overall.

This phenomenon is often described in NLP literature as a "faithfulness failure"—where the model generates a label that is plausible on the surface but contradicts the deeper semantic meaning of the input text [15, 2, 14, 22]. In educational contexts, this often manifests as the model over-relying on specific keywords (e.g., classifying any question starting with "Why" as a *Press for Reasoning*) rather than analyzing the true pedagogical intent [40].

2.3 LLM Reasoning as Diagnostic Signals

Recent literature suggests that LLMs possess an internal awareness of their own correctness, which can be elicited through probability estimation [17] or verbalized confidence scores [35, 16, 19]. However, explicit confidence prompts do not always capture the nuance of model failure, and existing mitigation strategies often rely on sampling consistency. Methods such as *SelfCheckGPT* [23] or *Self-Consistency* [41] generate multiple responses for the same input and aggregate them to filter out outliers. While effective, these methods increase computational cost linearly with the number of samples (N), making them prohibitively expensive for real-time educational feedback.

Consequently, a growing body of work suggests that the structure and content of model-generated explanations can serve as diagnostic signals for identifying incorrect predictions. In prior literature, this signal is often studied through reasoning traces—step-by-step intermediate reasoning sequences produced during inference, commonly in chain-of-thought or process supervision settings. While [38] caution that such traces may function as unfaithful post-hoc rationalizations, recent work in process supervision has nevertheless shown that properties of these traces, such as length and linguistic hedging, correlate with model uncertainty and error [44, 34, 32]. In contrast, the explanations analyzed in this study are elicited rationales: short, post-hoc justifications generated alongside a predicted label rather than procedural traces of internal inference. We do not assume these rationales faithfully reflect latent reasoning processes. Instead, we treat them as observable linguistic artifacts whose structure may still provide diagnostic information. Building on insights from trace-based work, we operationalize these linguistic markers within the educational domain to filter false positives in classroom discourse analysis, without the computational overhead of multiple sampling or process-level supervision.

2.4 Linguistic Analysis of Generated Text

To understand the nature of these failures, researchers have turned to linguistic analysis tools like Linguistic Inquiry and Word Count (LIWC) [28]. LIWC counts words in psychologically meaningful categories (e.g., affect, cognition, certainty) and has been widely used to analyze student essays, forum posts, and increasingly, AI-generated text. Prior work evaluating human-AI differences suggests that AI-generated text often exhibits distinct linguistic profiles, such as lower variance in vocabulary and specific patterns of hedging when the model is "confabulating" or hallucinating [48]. Similarly, [44] identified that uncertainty in reasoning is often marked by increased verbosity and "hedging" language. Our work extends

this methodology to the validation of automated coding. By applying LIWC analysis to LLM reasoning, we isolate the specific linguistic markers—such as high "insight" and low "causation"—that differentiate valid, grounded classification from misclassified outputs.

3. THE CURRENT STUDY

The increasing use of Large Language Models (LLMs) for automated discourse annotation has enabled educational researchers to analyze classroom dialogue at unprecedented scale. However, despite improvements in classification accuracy, LLM-based annotation pipelines continue to suffer from persistent misclassifications—particularly false positives—that can systematically bias downstream analyses such as sequential modeling and epistemic network analysis. Existing work has largely focused on improving model performance, with comparatively less attention paid to mechanisms for detecting when an automated annotation is likely incorrect.

The current study investigates whether model-generated explanations—elicited alongside predicted instructional move labels—can serve as a diagnostic signal for identifying annotation errors. Rather than treating LLMs as black-box classifiers, we examine whether the linguistic structure of the explanations they produce when justifying a label provides useful information about the correctness of that label. This framing positions explanation-based verification as a complementary reliability layer that operates independently of the original classification model and does not require additional sampling or access to model internals. We evaluate this approach in the context of automated coding of classroom discourse using a well-established Talk Moves framework. Specifically, we treat misclassification detection as a secondary supervised learning task: given an LLM's predicted label and its accompanying explanation, can we predict whether the label is correct relative to expert human annotations? In addition to assessing whether such a signal exists, we examine how robust it is across different state-of-the-art LLM architectures, whether it can be explained in terms of interpretable linguistic features, and whether performance improves when verification models are specialized for individual instructional constructs.

Guided by this framing, the study addresses the following research questions:

RQ1: Can the reasoning generated by LLMs serve as a reliable diagnostic signal for detecting misclassifications in educational discourse analysis?
RQ2: How robust is this reasoning-based verification signal across different state-of-the-art LLM architectures?
RQ3: What specific linguistic features within LLM reasoning are most predictive of classification correctness?
RQ4: Does training specialized models for specific constructs outperform a single generalist model in detecting misclassifications?

4. METHODOLOGY

The current study relies on a novel two-step method to explore improving annotations through classifying misclassifications. The first step, described in Section 4.2 uses a typical LLM qualitative coding scheme in which LLMs are prompted to annotate a data set, in this case classroom transcripts with *Talk Moves* derived from accountable talk theory. As part of this step, the LLMs are also prompted to provide reasoning for their classification. In the second step, described in Section 4.3, we trained machine learning models to detect misclassifications (false positives) using the reasoning output.

4.1 Talk Moves Data Set

We drew on the previously published *TalkMoves Dataset*, which contains classroom transcripts annotated and validated by expert educators and is described in detail in prior work [33]. For the present study, we used a stratified sample of 63 transcripts covering multiple grade bands (sampling procedure described below). The corpus consists of mathematics instruction transcripts from authentic K–12 settings, including whole-class discussions, small-group work, and online lesson environments. Transcripts were human-transcribed, speaker-segmented, and labeled at the utterance level using a six-construct *Talk Moves* scheme aligned with the Accountable Talk framework. Constructs associated with accountability to the learning community include *Keeping Everyone Together*, *Getting Students to Relate to Another's Ideas*, and *Restating*. Constructs associated with accountability to content knowledge include *Pressing for Accuracy*. Constructs associated with accountability to rigorous thinking include *Revoicing* and *Pressing for Reasoning*. Utterances that did not exhibit any of these discourse moves were assigned a *None* label.

The human-produced labels were treated as the reference standard for all performance comparisons. These labels were generated by trained mathematics educators using an established Accountable Talk coding protocol, with prior reporting showing very high inter-rater agreement (Cohen's $\kappa > 0.90$) [33]. For model evaluation, we reorganized transcripts into context windows of up to 20 utterances, a preprocessing step designed to fit model context limits while maintaining local discourse continuity.

To manage computational and API cost, we conducted the study on a structured subsample rather than the full corpus. We applied proportional stratified random sampling to select 800 focal utterances so that the class distribution matched the original Talk Move label frequencies. Each focal utterance was then augmented with its surrounding dialogue (up to 20 preceding turns and one following turn), and overlapping windows were consolidated into continuous segments. Because context windows were included by design, the final set exceeded the initial focal count: about 79.5% (10,522) were unique teacher utterances with valid Talk Move codes, and the remaining 20.5% were additional turns retained to preserve conversational context.

4.2 Annotation Procedure

We annotated the data sample for six talk moves constructs using four state-of-the-art Large Language Models (LLMs): **GPT-5** (OpenAI), **Claude 4.5 Sonnet** (Anthropic), **Gemini 2.5 Pro** (Google), **o3** (OpenAI). We employed a simple **zero-shot prompting strategy** with definitions of TalkMoves taken from

the Talk Moves coding schema[1]. The prompt included a request to "provide a concise explanation in the 'Reasoning' field only when a Talk Move is present." This generated a diverse dataset of LLM reasoning, ensuring the classifier was trained on a rich distribution of valid and invalid arguments across different generation attempts. This process generated an initial pool of over 30,817 LLM-predicted annotations. For 518 annotations (1.8%), the models did not produce reasoning, resulting in a total of 30,300 annotations used in the analysis.

4.3 Misconception Classification

4.3.1 Study Context & Data Partitioning

The dataset consists of $N = 30,300$ instances of teacher-student interactions, derived from a stratified sample of classroom logs. Each instance includes a target variable, `IsCorrect` (binary: 0 or 1), establishing ground truth for the correctness of the LLM's classification. To ensure robust evaluation, we employed a stratified random sampling technique to partition the data into a Training Set (D_{train}): 80% of the corpus ($n = 24,190$), used for model fitting and hyperparameter tuning; and a Test Set (D_{test}): 20% of the corpus ($n = 6,110$), held out strictly for final performance evaluation. Stratification was performed based on the `IsCorrect` label to preserve the class distribution (Correct vs. Incorrect) inherent in natural model processing. Transcript IDs were used as grouping constraints during partitioning so that utterances derived from the same transcript were not distributed across both training and test sets.

4.3.2 Feature Representation Details

The primary input variable X is the unstructured text of the reasoning for the annotation generated by the LLM. We transformed this raw text into a numerical feature space using Term Frequency-Inverse Document Frequency (TF-IDF) vectorization. The feature space dimension V had a maximum of 3,227 unigrams ($|V| = 3,227$), based on the max unigrams in the corpus. Stop-word removal (English) was applied to reduce feature noise. Preliminary experiments comparing Unigram vs. Bigram/Trigram architectures yielded negligible performance improvements ($< 0.2\%$ $\Delta F1$), justifying the parsimonious choice of a unigram-only model.

4.3.3 Classification Algorithms

We implemented and compared five supervised classification algorithms to predict misclassification. All models incorporated class weighting (`class_weight = 'balanced'`) to penalize misclassification of the minority class proportionally to its frequency.

Logistic Regression (Baseline): Selected for its interpretation capabilities (coefficient analysis) and efficiency in high-dimensional sparse spaces.
Random Forest (Ensemble): A bagging ensemble of 100 decision trees. This model was utilized to capture non-linear feature interactions (e.g., the conjunction of "not" and "verbatim") that linear models might miss.
Support Vector Machine (Linear SVM): A max-margin classifier. We utilized a linear kernel to handle the high dimensionality of the TF-IDF space efficiently.

[1]`https://github.com/SumnerLab/TalkMoves/blob/main/Coding\%20Manual.pdf`

Gradient Boosting (GBM): A boosting ensemble that builds simplified trees sequentially to minimize residual error, included to test robustness against hard-to-classify examples.
Multinomial Naive Bayes: A probabilistic baseline relying on Bayes' theorem with an assumption of feature independence, traditionally strong for text classification.

4.4 Per-Construct Model

To address the heterogeneity of linguistic correctness markers across different TalkMoves, we additionally trained one model per construct. This approach decomposes the global classification problem into a set of distinct sub-problems. Let C be the set of all possible TalkMoves Constructs (e.g., "Pressing for Reasoning", "Revoicing"). For each construct $c \in C$, we defined a specialist subset $D_c \subset D_{train}$ such that:

$$D_c = \{(x_i, y_i) \mid \text{PredictedLabel}(x_i) = c\} \tag{1}$$

For the top $k = 6$ most frequent constructs, we trained an independent Random Forest classifier M_c exclusively on D_c. At inference time, the system routes a new instance x_{new} to the appropriate model M_c based on its predicted label. This allows M_c to learn a localized vocabulary of correctness—for instance, weighting the term "classmate" heavily for *Getting Students to Relate*, a signal that might be irrelevant or noisy for *Pressing for Accuracy*.

4.5 Linguistic Features (LIWC)

To systematically analyze the cognitive and rhetorical structure of LLM reasoning, we processed all reasoning outputs using the Linguistic Inquiry and Word Count (LIWC) framework [28]. We focused on three theoretically relevant constructs: (a) logical grounding, (b) epistemic calibration, and (c) cognitive self-referential framing We selected these linguistic feature constructs to operationalize dimensions of reasoning quality and epistemic stance in LLM-generated explanations. Prior work on model explanations and uncertainty suggests that incorrect or weakly grounded reasoning is often characterized not by syntactic simplicity, but by epistemic hedging, metacognitive narration, and reduced evidential linkage between claims and conclusions [6, 15].

Causation markers (e.g., *because, therefore, implies*) were included to measure explicit premise–conclusion linking. In instructional move classification, correct labels require mapping observable discourse evidence to construct definitions. Reasoning that explicitly encode causal or justificatory structure may be more likely to reflect evidence-based classification rather than keyword matching or surface heuristics [3].

Differentiation markers (contrastives, discrepancies, and exclusions; e.g., *but, however, except, should*) were included to measure contrastive and error-checking structure. Many construct definitions involve ruling out alternative interpretations (e.g., distinguishing revoicing from restating). We therefore tested whether valid reasoning exhibit greater contrastive structure. This composite category captures logical branching and boundary-setting language.

Tentativeness markers (e.g., *might, could, possibly*) were selected to capture epistemic hedging and uncertainty expression. Work on verbalized model uncertainty shows that LLMs frequently externalize low confidence through modal and hedge language [15]. We therefore treat tentativeness

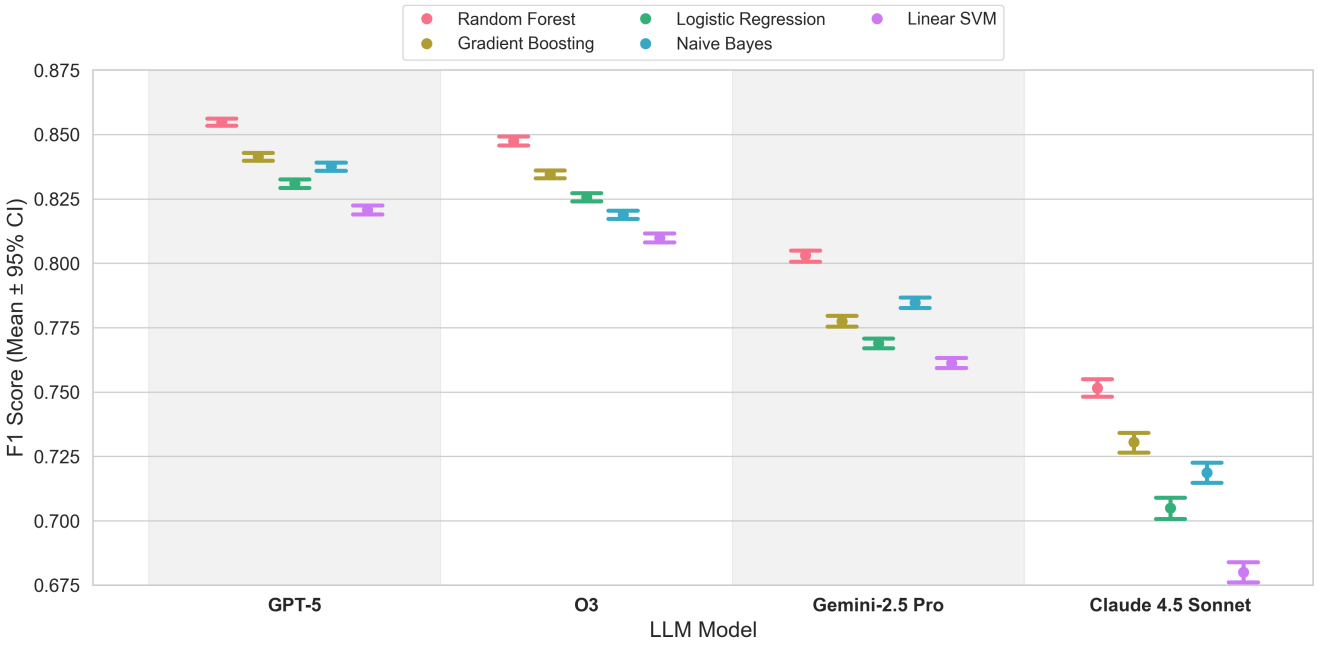

Figure 1: Cross-Model Detection Performance. A comparison of F1 scores for five supervised classification algorithms (Logistic Regression, Random Forest, SVM, Gradient Boosting, Naive Bayes) across the four target LLMs (Claude 4.5 Sonnet, Gemini 2.5 Pro, GPT-5, o3). The Random Forest classifier (pink points) consistently outperforms linear baselines across all generative models. Error bars represent 95% confidence intervals.

density as a proxy for internal uncertainty signals that may correlate with misclassification risk [6].

Insight markers (e.g., *think, realize, know*) were included to detect metacognitive and self-referential reasoning frames. For our proposal, these marks might be indicative of stances rather than empirically grounded evidence. Prior work on stance and epistemic modality shows that verbs such as "think" and "know" are linguistic markers of subjective commitment or metacognitive framing rather than text-based evidential support, and have been used as features in uncertainty/stance tasks in NLP [25].

Together, these feature groups map onto complementary dimensions for exploratory analysis of LLM reasoning and its association with misclassification. This design enables direct testing of whether correctness is primarily associated with logical grounding versus rhetorical or metacognitive elaboration. Finally we examine the differences in reasoning length between correct and incorrect annotations. A common heuristic in prompt engineering is that "more reasoning equals better performance" [42]. However, this is often used in the context of 'chain-of-thought' reasoning. Less is known about how explanation length behaves when models are prompted to justify a label they have already produced. Accordingly, we analyze the distribution of rationale lengths for correct and incorrect annotations to assess whether explanation length provides a useful signal for verification.

5. RESULTS

5.1 Can LLM Reasoning Predict Correctness? (RQ1)

First, we evaluate whether the LLM reasoning text contains sufficient signal to verify the correctness of an LLM's label by benchmarking classifier performance on the holdout sample. As shown in Table 1, all models achieved high predictive accuracy, with F_1 scores ranging from 0.79 to 0.83. The Random Forest classifier yielded the top performance, achieving a Precision of 0.807 and a Recall of 0.854. This high recall is particularly critical in an educational context, as it minimizes the risk of inadvertently discarding valid Talk Moves during the verification process. Overall, these results provide strong evidence that LLM reasoning contains latent linguistic markers that effectively signal classification accuracy.

Table 1: Performance of Verification Classifiers. Evaluation on the held-out test set ($N = 6,110$). Random Forest yields the highest F1 score.

Model	Precision	Recall	F1	Accuracy
Random Forest	**0.807**	0.854	**0.830** ($\pm$ 0.009)	**81.1%**
Gradient Boosting	0.764	**0.867**	0.812 ($\pm$ 0.010)	78.3%
Naive Bayes	0.783	0.832	0.807 ($\pm$ 0.010)	78.5%
Logistic Regression	0.806	0.797	0.802 ($\pm$ 0.010)	78.7%
Linear SVM	0.798	0.780	0.789 ($\pm$ 0.011)	77.4%

To contextualize this prediction task, consider the following two examples of model-generated reasoning drawn from our dataset, only one of which is correct.

"The teacher rephrases the student's question, clar-

ifying the idea that the measurement might not be the whole volume because the object is floating." — **Reasoning A** (Gemini 2.5 Pro)

"The teacher explicitly asks the student to provide the reasoning ('why') for their answer." — **Reasoning B** (Gemini 2.5 Pro)

Recognizing that Reasoning A accompanied a misclassification, while Reasoning B presents a correct justification, is not obvious. Notice that the incorrect reasoning leaks uncertainty through hedging or speculative language ("might not be"), whereas the correct reasoning is more direct and grounded in observable instructional actions ("explicitly asks"). We formally analyze linguistic markers in Section 5.3.

5.2 Robustness Across LLMs (RQ2)

We evaluated classifier performance across the four distinct LLMs used for annotation: GPT-5, o3, Gemini 2.5 Pro, and Claude 4.5 Sonnet. As illustrated in Figure 1, all misconception classification models performed well ($F1 > 0.67$) on classifications from all LLMs. The Random Forest classifier consistently outperformed the other models across all four LLMs. This dominance was particularly pronounced for annotations generated by Claude 4.5 Sonnet, where other models dropped to $F1$ scores as low as 0.70, while the Random Forest classifier maintained a significantly higher performance of 0.75. This performance gap indicates that the linguistic features distinguishing valid from invalid reasoning may be inherently nonlinear, necessitating the complex decision boundaries of ensemble methods regardless of the source LLM.

While the detection method remained effective globally, the absolute detectability of misclassifications varied by source model. Misclassifications generated by reasoning models like o3 and GPT-5 were the easiest to detect, with the Random Forest achieving $F1$ scores exceeding 0.85. The strong agreement between linear and nonlinear models in these conditions suggests that errors in these models may be marked by distinct, easily separable lexical artifacts. In contrast, misclassifications from Claude 4.5 Sonnet proved more challenging to verify. In these cases, the generated reasoning may be more linguistically homogenous with valid reasoning, reducing the effectiveness of simple keyword-based detection. Overall, while the approach performs moderately well across the board, performance is maximized when applied to models that exhibit distinct and detectable misclassifications.

5.3 Linguistic Markers of Misclassification (RQ3)

Our multidimensional linguistic analysis reveals distinct cognitive profiles for valid versus invalid reasoning. As illustrated in Figure 2, correctness in mathematical reasoning is not signaled by complexity or "insight," but by the prosaic density of causal logic.

5.3.1 Metacognition as a Negative Signal

Insight was a significant *negative* signal ($p < 0.001$). Reasoning that contained high densities of metacognitive terms like "I think," "I realize," and "understand" were overwhelmingly more likely to be incorrect. This finding identifies a specific

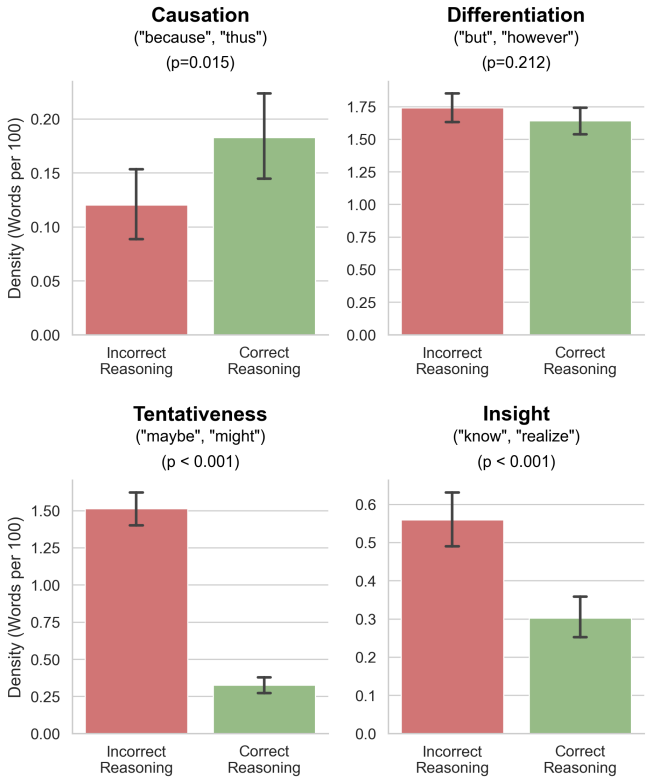

Figure 2: Linguistic Markers of Correct vs. Incorrect Reasoning. Average density of linguistic features (words per 100 words) in correct (orange) vs. incorrect (blue) instructional move reasoning. Causation ("therefore", "because") is the primary predictor of correctness ($p = 0.015$), indicating that explicit logical structure aligns with accurate problem solving. Conversely, Tentativeness ("might", "could") and Insight ("believe", "think") are more prevalent in incorrect responses ($p < 0.001$), suggesting that models use hedging and metacognitive language as "filler" when reasoning is flawed or uncertain. Differentiation ("but", "however") showed no significant difference ($p = 0.212$), appearing equally in both valid and invalid arguments. Error bars represent 95% confidence intervals.

mode of failure: mere "performative reasoning." When the model lacks a clear logical path, it compensates by narrating its own cognitive state, filling the reasoning with vacuous self-reflection instead of derivation.

5.3.2 Verbalized Uncertainty and Calibration

We examined *Tentativeness* (e.g., "might," "could," "possibly") to determine if models effectively signaled their uncertainty and found a statistically significant trend where incorrect answers contained a higher density of tentative language. This indicates a degree of successful calibration: when the model is less certain of its reasoning, it employs more hedging. Conversely, correct reasoning was characterized by declarative, confident assertions, suggesting that high certainty (low tentativeness) is a reliable linguistic proxy for mathematical accuracy. This "Verbalized Uncertainty" [20] serves as a potent diagnostic signal, allowing the classifier to detect when the model is "guessing" based on weak correlations rather than identifying a clear signal.

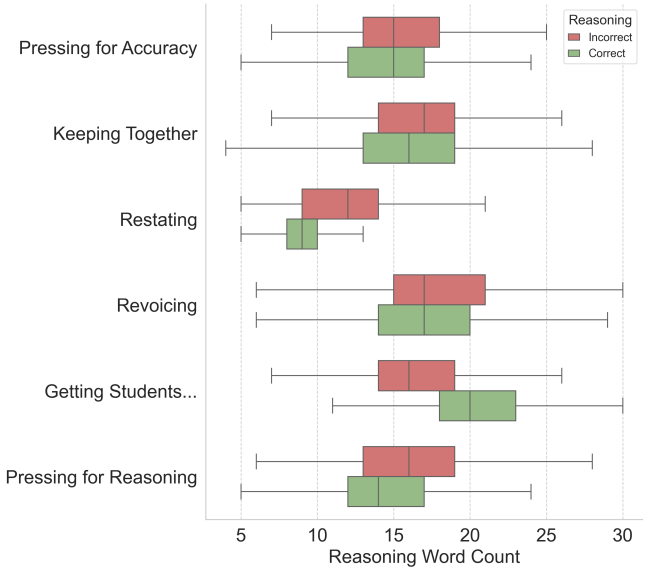

Figure 3: Reasoning Length Distribution. Distribution of reasoning lengths for Correct (Green) vs. Incorrect (Red) predictions. All differences are statistically significant ($p < 0.05$). Reasoning for correct responses is generally more concise than for incorrect responses, with the notable exception of *Getting Students to Relate*, where correct identification of complex student-to-student interactions requires significantly longer explanations.

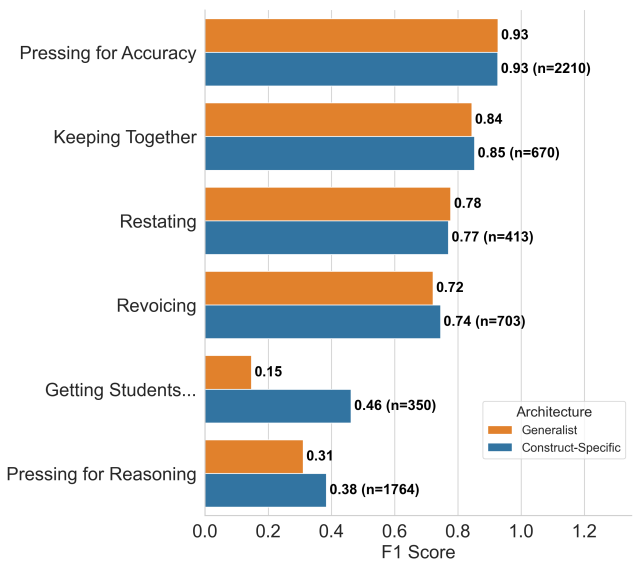

Figure 4: Performance Comparison: Generalist vs. Construct-Specific Models. While generalist models perform comparably on constructs like *Pressing for Accuracy* ($F1 \approx 0.93$), construct-specific models provide critical gains for complex moves. Notably, for *Getting Students to Relate* ($n = 350$), the specialist architecture triples the F1 score (0.46 vs. 0.15), recovering signal that is otherwise drowned out by global patterns.

5.3.3 *Causal Chaining and Logical Validity*

Valid mathematical derivations are fundamentally characterized by explicit causal structures. Likewise, we found that correct responses exhibited a significantly higher ($p = 0.015$) density of Causation markers (e.g., "therefore," "because," "implies," "yields") than misclassified responses. Correct reasoning contained a mean density of 0.18 causal markers per 100 words, compared to only *0.12* for misclassified responses. This finding confirms that accuracy is strongly correlated with the use of directional logical connectors: correct models explicitly link premises to conclusions, whereas incorrect models often present disconnected assertions without the requisite connective tissue.

5.3.4 *Conceptual Differentiation and Structural Complexity*

We analyzed the density of Differentiation markers (e.g., "but," "however," "except") to determine if valid reasoning involved more robust error-checking or case handling. The analysis yielded a null result ($p = 0.212$), with no significant difference in differentiation density between correct ($\mu = 1.63$) and incorrect ($\mu = 1.74$) reasoning. This indicates that incorrect reasoning is often just as syntactically complex as valid reasoning. Reasoning of misclassified responses frequently employs contrastive language not to distinguish valid mathematical constraints, but rather to express confusion or hedge between incorrect options, resulting in a linguistically sophisticated but logically flawed explanation.

5.3.5 *Reasoning Length as a Signal*

Besides the LIWC analysis, we also evaluated whether the reasoning length analysis differed based on correct or incorrect responses. Figure 3 reveals distinct verbosity profiles for valid vs. invalid predictions: For the majority of constructs (e.g., *Pressing for Reasoning*, *Keeping Everyone Together*), valid reasoning (Green boxplots) is **significantly shorter** than incorrect ones (Red boxplots). This suggests that valid reasoning is precise, evidence-based, and directed. In contrast, misclassified reasoning tends to be verbose and circuitous, often characterized by the model "waffling" or attempting to rationalize a weak connection with filler text. The "Relating" Exception: The sole statistically significant exception is *Relating to Others*, where correct reasoning is longer ($Median \approx 22$ words) than misclassifications. This makes intuitive sense: correctly identifying a "Relate" move requires describing a complex interaction between the teacher, Student A, and Student B. A misclassification in this construct often fails to capture this tripartite structure, resulting in shorter, more vague reasoning.

5.4 Construct-Specific Detection (RQ4)

Finally, we investigated whether we could optimize performance by training Construct-Specific Verifiers—dedicated Random Forest models trained exclusively on partitions of the dataset corresponding to a single TalkMove. As illustrated in Figure 4, these targeted models demonstrated distinct performance profiles based on construct complexity. We observed high verification reliability for **Pressing for Accuracy** ($F1 = 0.86$) and **Restating** ($F1 = 0.78$). This indicates that for moves defined by specific keywords (e.g., "exact words", "vocabulary"), the classifier is effective at distinguishing valid reasoning from misclassifications. In contrast, inferential

constructs proved more challenging. **Pressing for Reasoning** achieved an F1 of 0.48. Similarly, **Getting Students to Relate to Another's Ideas** ($n = 1,918$) achieved an F1 of 0.46. While low in absolute terms, this represents a significant signal recovery compared to the generalist baseline ($F1 = 0.15$), confirming that training on a dedicated subset captures distinct tripartite references (Teacher-Student-Student) that are otherwise diluted in the global dataset.

5.4.1 Linguistic Markers of Correctness: A Construct-by-Construct Analysis

To understand *what* the specialist classifiers are learning beyond global heuristics, we analyzed feature importance scores to extract the "vocabulary of correctness" for each TalkMove. Table 2 details the distinguishing signatures and provides in-context examples of correct vs. incorrect reasoning.

This analysis reveals that reasoning for each pedagogical move has a *linguistic fingerprint*:

Explicit Moves (e.g., Restating): Reliability is driven by correct reasoning containing synonyms for exactness (*verbatim, repeats, word-for-word*). Misclassifications typically involve words related to modification (*clarify, rephrase*), indicating the model is confusing a repetition with a re-explanation.

Inferential Moves (e.g., Pressing for Reasoning): The signal relies on causal language (*because, justify, why*). Misclassifications often use vague cognitive terms (*thinking, thoughts*), failing to distinguish between a general question and a specific request for evidence.

Social Moves (e.g., Relating, Keeping Together): Correctness is marked by collective nouns (*class, peer, classmate, we*). The absence of these group-orienting terms is a strong predictor of misclassifications, where the model falsely attributes a social move to a generic teacher-student interaction.

6. DISCUSSION

This study shows that model-generated rationales (i.e., elicited explanations produced alongside automated discourse labels) contain systematic linguistic signals that predict whether an LLM's annotation is correct. Across various LLMs, prediction models, constructs, and verification architectures, we find that these rationales support reliable detection of misclassifications (F1 $\approx$ 0.83), demonstrating that error and uncertainty are frequently externalized when models are prompted to explain their decisions. This finding aligns with prior work showing that reasoning and verbalized confidence signals encode information about model uncertainty and correctness [17, 35, 44]. Rather than treating explanations as auxiliary artifacts, our results position them as a practical verification layer that can be leveraged to improve the reliability of large-scale automated coding in EDM, where LLM-based classification is increasingly used for complex, high-inference constructs [18, 26].

These findings contribute to ongoing debates about the role and reliability of LLM explanations. Prior work has cautioned that explanations may function as post-hoc rationalizations that are not causally responsible for model predictions [38, 15, 2]. Our results support a more application-oriented interpretation: even when elicited rationales are not guaranteed to be faithful to internal model mechanisms, their linguistic structure remains predictively diagnostic of correctness. In high-inference educational coding tasks where reliability has been shown to vary widely across prompts and constructs [24, 40], valid annotations are more often supported by rationales grounded in observable textual evidence and explicit causal logic, whereas incorrect annotations more frequently rely on speculative or self-referential language. This enables downstream verification without requiring access to model internals or computationally expensive multi-sample strategies such as self-consistency [41] or SelfCheck-style approaches [23].

The linguistic analysis reveals a consistent pattern across models and constructs. Correct annotations are associated with concise, declarative rationales that explicitly connect utterance features to constructs using causal connectors and evidence-grounded justification. In contrast, misclassifications are marked by increased epistemic hedging, performative metacognitive language, and greater verbosity. This pattern is consistent with prior analyses showing that LLM uncertainty and error are often expressed through longer, more hedged reasoning traces [44] and with broader accounts of confabulation and faithfulness failures in generated explanations [15, 2, 48]. LIWC-based and related linguistic profiling work further suggests that AI-generated text exhibits systematic shifts in hedging, insight, and causation markers when semantic grounding is weak [28, 48]. Importantly, incorrect rationales in our data are not linguistically simplistic; they are often syntactically complex and rhetorically fluent, reinforcing that surface sophistication alone is not a reliable proxy for validity.

We also observe substantial variation in detectability across LLM architectures. Misclassifications generated by GPT-5 and o3 were comparatively easy to identify, while errors from Claude 4.5 Sonnet were more difficult to distinguish from correct annotations. This result is consistent with prior findings that LLM annotation reliability varies significantly across models and prompt formulations [18, 24]. It also suggests that as models improve in rhetorical fluency, incorrect rationales increasingly approximate the discourse patterns of correct ones, creating a moving-target problem for explanation-based verification. Explanation-based detection remains effective, but its discriminative margin may narrow as stylistic quality improves. This reinforces the need to combine rationale-based verification with complementary approaches such as calibration signals and construct-specific prompting strategies [17, 35].

Our results further highlight a trade-off between model generality and construct specificity in LLM-based coding. Prior work shows that LLM performance drops for ambiguous or high-inference constructs and that targeted prompt and example design can substantially improve results [36, 29, 18]. Consistent with this pattern, we find that specialist verifiers yield substantial gains for certain discourse constructs, suggesting a practical pipeline in which general-purpose LLM annotation is paired with construct-targeted verification layers. Linguistic profiles of correct rationales—such as explicit relational or causal structure—provide actionable features

Table 2: Linguistic Markers of Correctness (TF-IDF Analysis). A breakdown of the lexical markers that distinguish correct reasoning from misclassifications across six TalkMoves. (+) denotes positive predictors, (-) denotes negative predictors.

Construct	Key Markers	Correct Example (+)	Incorrect Example (-)
Pressing for Reasoning	(+) *justify, because, explain why* (-) *share, thinking, thoughts*	"The teacher asks 'How do you know', prompting the student to explain their **justification**."	"The teacher prompts students to write... eliciting explanation of their **thinking**."
Restating	(+) *verbatim, repeats, exactly* (-) *clarify, rephrase, confirm*	"The teacher repeats the student's response ('No') **verbatim**."	"The teacher repeats a key part... for **clarification**, changing the words."
Revoicing	(+) *paraphrases, repeats, wording* (-) *question, check, understanding*	"The teacher **paraphrases** the student's idea... changing **wording** to clarify."	"The teacher reframes... by suggesting 'dis' might mean 'wrong,' checking **understanding**."
Pressing for Accuracy	(+) *precise, specific, term* (-) *check, confirm, correctness*	"The teacher asks the student to use the **precise** mathematical **term**."	"The teacher **checks** whether a specific way of writing is valid..."
Keeping Everyone Together	(+) *class, shared, orienting* (-) *agreement, explain, question*	"Prompts a student to **read aloud** to the **class**, orienting listeners."	"The teacher asks a **question** to ensure all students are following."
Getting Students to Relate	(+) *classmate, peer, react* (-) *connect (vague), link, interaction*	"The teacher explicitly asks students to **react** to [Student]'s idea."	"The teacher asks students to **connect** their answer to the previous problem."

for designing these construct-specific verifiers and prompts.

Finally, these results have direct implications for educational data mining pipelines that rely on automated discourse annotation. LLM-based coding is increasingly used to analyze tutoring dialogue, classroom discourse, and other forms of unstructured educational text [1, 47, 37, 43]. However, prior studies document persistent false positives and construct-level reliability gaps [40, 24]. Because downstream methods such as discourse modeling and instructional quality measurement are sensitive to systematic labeling errors, explanation-based verification offers a scalable quality-control layer. By using rationale-derived signals to triage outputs, high-confidence annotations can be accepted automatically while flagged cases are routed for human review or construct-specific reanalysis. This selective acceptance strategy supports scalable annotation while preserving inferential validity, advancing more trustworthy deployment of LLMs for educational discourse analysis.

6.1 Limitations

Our study focused on a specific math instructional context. While the concept of detection via reasoning is likely generalizable, the specific vocabulary (e.g., "numerator", "fraction") may be domain-specific. Future work should test the transferability of these Correctness markers to other domains, such as English Language Arts or Science. All rationales analyzed in this study were elicited through a specific prompting strategy that explicitly asked models to justify their labels. Different prompt formulations, levels of instruction, or constraints on explanation length may influence how uncertainty and error are linguistically expressed. As a result, the strength and form of the verification signal may vary under alternative prompting regimes. Our models operate on textual features of model-generated rationales using traditional NLP representations. While this design choice improves interpretability and computational efficiency, it does not capture deeper semantic or discourse-level structure that may further distinguish valid from invalid explanations, particularly for high-inference constructs. More expressive representations may improve detection performance but also introduce additional complexity and cost.

7. CONCLUSION

As LLMs become increasingly integrated into educational data mining workflows, the reliability of automated annotation remains a central challenge. This work shows that when models are prompted to justify their labels, the resulting model-generated rationales contain systematic linguistic signals that can be used to detect misclassifications at scale. Across multiple state-of-the-art LLMs, instructional constructs, and verification architectures, we demonstrate that these rationales support accurate prediction of annotation correctness, offering a practical mechanism for quality control in automated discourse analysis.

Beyond performance gains, our findings provide insight into how and when automated annotations fail. Correct annotations are supported by concise, causally grounded explanations that reference observable features of the discourse, while incorrect annotations are more often accompanied by hedging, performative metacognitive language, and increased verbosity. These patterns suggest that elicited explanations externalize model uncertainty in a way that is both systematic and exploitable, even when explanations are not guaranteed to reflect internal decision processes.

From an applied perspective, this work reframes explanations from passive artifacts into actionable verification signals. Rather than treating LLM outputs as binary predictions, ed-

ucational researchers can leverage model-generated rationales to selectively accept high-confidence annotations and flag uncertain cases for further review. This approach enables scalable annotation while mitigating the propagation of false positives into downstream analyses such as sequential modeling, instructional quality measurement, and network-based representations of classroom discourse.

More broadly, this study contributes to ongoing discussions about the role of explanations in machine learning systems. While explanations may not always be faithful representations of internal reasoning, our results show that they can nonetheless be predictively useful for assessing correctness in real-world, high-inference tasks. By operationalizing explanation-based verification in an educational setting, this work offers a practical path toward building more trustworthy, transparent, and robust LLM-powered analytics for learning and instruction.

ABSTRACT

Student models in intelligent tutoring systems (ITS) often rely on large-scale behavioral data (e.g., correctness, response time), which provides only indirect evidence of cognition. While multimodal data such as think-alouds or screen recordings can offer richer insight into students' cognitive states, such data is rarely available at scale, limiting the practicality of multimodal models. To address this, we leverage Learning Using Privileged Information (LUPI) framework for cognitive state modeling in ITS. Our approach incorporates high-quality think-aloud data and written action descriptions from a subset of students at training time to inform model decision boundaries, while using only behavioral data at inference. This setup mimics real-world deployment where rich modalities are unavailable for most learners. We evaluate this method in modeling rule learning, an established framework for conceptual development during problem solving, and find improved predictive accuracy, particularly for nuanced cognitive states not well captured by behavioral logs alone.

Learning Using Privileged Information, Rule Learning, Multimodal Learning Analytics

1. INTRODUCTION

Interactive learning platforms such as intelligent tutoring systems (ITS) aim to provide personalized learning support by modeling students' knowledge, behavior, and cognitive states [38]. These models are often built using large amounts of data collected during student interactions with the system. Among these, behavioral log data such as correctness, response time, or hint usage are the most widely used sources of information, largely because they are easy to collect and available across many systems. However, while behavioral data are abundant and convenient, they are also discrete and indirect, often failing to capture the more subtle or continuous aspects of learners' cognitive processes [19].

In recent years, the field has increasingly turned to multimodal approaches to capture richer representations of student learning [3, 10, 13]. These approaches integrate behavioral logs with other data sources such as eye tracking, facial expressions, neural signals, and verbal protocols to gain deeper insight into students' thought processes and cognitive states. Among these, think-aloud protocols are particularly valuable for identifying real-time cognitive activity due to their interpretability [21]. Think-aloud protocols are widely used across HCI and cognitive science as a method for capturing users' internal reasoning in real time [14, 28]. They involve asking individuals to verbalize their thoughts while performing a task in order to gain access to moment-to-moment reactions and cognitive processing that are otherwise difficult to infer. In educational contexts, think-aloud protocols serve a similar purpose: they reveal how learners engage with problems, what they understand, and where they struggle. This form of verbal data has been shown to provide insights into learners' cognitive processes, and specifically in uncovering processes like self-regulated learning strategies [17, 43] and metacognitive monitoring and control [25, 31] that remain invisible in log data. Complementing these verbalizations, another heavily used modality is external observations which captures behaviors that learners may not articulate explicitly. This may include researcher coding of video data, screen recordings, or in situ observations of classroom behaviors. Prior work has shown such observations can reveal cognitive and affective states, and instances of disengagement [1, 27].

Even though multimodal methods are extremely helpful in providing a broader picture of students' cognition, a key limitation of many multimodal methods is that they rely on non-deployable signals or data that are easy to collect in controlled lab settings, but infeasible for real-world environments. As a result, models trained on rich multimodal data often suffer from limited generalizability and are difficult to apply in practice [26]. To address this challenge, we propose framing cognitive state modeling within the Learning

Using Privileged Information (LUPI) paradigm [39]. LUPI is a machine learning technique in which models are trained using additional information, called privileged information, that is available only at training time but not at test time. This privileged information can include richer or more explanatory features that help the model learn a better decision boundary during training. At inference time, the model operates solely on the standard input features. It ensures generalization while benefiting from the additional insight gained during training. In this work, we hypothesize that LUPI enables the use of rich but harder-to-collect information such as verbal think-alouds or action descriptions during model training, while maintaining deployability by relying only on behavioral data at inference time. In doing so, it offers a powerful approach to bridge the gap between what learners experience and what can be captured externally.

In this work, we model phases of rule learning [7] as our target cognitive states. The rule learning framework offers a formalization for cognitive states, such as moving from unfamiliarity to partial understanding to fluent application, and reflects core aspects of skill acquisition [33]. Our key contributions are as follows: (1) We introduce a novel application of LUPI to model rule learning states in ITS contexts, using multimodal data that combines behavioral logs with verbal protocol data. (2) We demonstrate that incorporating verbal protocol data during training significantly improves model performance, particularly for cognitive states that are challenging to infer from behavior alone.

2. RELATED WORK

2.1 Multimodal Student Modeling

Beyond behavioral log data, researchers have increasingly turned to multimodal approaches to capture a richer picture of learning processes. These approaches integrate multiple data streams such as eye-tracking, speech, hand-writing to improve student modeling and provide insight into cognitive and affective states that are difficult to detect from logged behavioral information alone [8].

Textual data has been widely explored within multimodal student modeling, since it provides direct evidence of learners' reasoning and cognitive states in real time [2]. Within this broader category, think-aloud protocols represent a particularly valuable form of textual data. Recent advances in educational data mining and AI in education have increasingly incorporated think-aloud protocols as rich sources of cognitive and metacognitive data for machine learning applications. Zhang et al. demonstrated the potential of large language models to automatically detect self-regulated learning (SRL) behaviors from transcribed think-alouds, enabling predictive modeling of learning strategies without the need for manual annotation [43]. Similarly, Li et al. leveraged topic modeling and supervised classification on think-aloud transcripts to predict students' reasoning activities during computer-assisted learning, showing that TAP-derived features can robustly model cognitive patterns [21]. Tabarsi et al. triangulated verbal and behavioral data, using coded think-aloud segments alongside video and interaction logs to train data-driven detectors for identifying programming difficulties among novice learners [35].

Another complementary modality is human observation, where researchers code student behaviors to capture aspects of learning not visible in interaction logs. Early work in ITS relied heavily on expert observers to identify cognitive and affective states. For example, Baker et al. [1] used classroom observations of Cognitive Tutor users to code when students were gaming the system, and these observations provided the training data for generalizable automated detectors. Similarly, the Baker-Rodrigo Observation Method Protocol (BROMP) [27] has been used to code affective states such as boredom, frustration, and confusion. Other studies have relied on expert coding of more complex behaviors from screen replays or video recordings [34]. D'Mello et al. combined human annotation of affect during learning sessions with system logs to train multimodal models of affect detection [12]. Paquette et al. [29] examined expert coding of disengagement in online learning environments. They showed that coders rely on contextual cues rather than isolated actions when making judgments about student behavior. Recent studies have explored human-coded observational data as features in predictive models. Tian et al. demonstrated how textual artifacts such as rubric-based classroom observations and field notes can be encoded and used in supervised learning to predict instructional quality and engagement [36]. Wu utilized graph convolutional networks (GCNs) on structured classroom observation datasets to evaluate teaching effectiveness at scale [42]. In another study, Petković et al. combined manual coding of teacher nonverbal behaviors with computer vision and machine learning techniques to assess instructional immediacy and its impact on student engagement [30]. In our work, we use written notes from screen recordings as a form of human observation. This allows us to capture detailed traces of students' actions during problem solving and relate them to underlying cognitive states.

2.2 Learning Using Privileged Information

The Learning Using Privileged Information (LUPI) paradigm was first introduced by Vapnik and Vashist [39]. The key idea is that during training, the model has access to additional *privileged* information that is not available at test time but can help the learner form a more accurate decision boundary. This setup mirrors real-world scenarios in which richer explanatory features (e.g., expert feedback, annotations, or multimodal data) are accessible during the development of a model but are impractical or impossible to collect consistently during deployment. Vapnik describes this idea as taking inspiration from human learning: a teacher may provide additional explanations, hints, or demonstrations when introducing a challenging concept, enabling the student to build a deeper understanding. However, once the student sits for an exam, these supports are no longer available, and the student must rely only on what they have internalized.

Researchers have used LUPI in a number of different HCI and educational settings. Vrigkas et al. [40] used LUPI for a human activity recognition task. They introduced a model that combined standard video features with additional data such as audio, pose data, or semantic annotations as privileged information. Their results showed that including this privileged information improved recognition accuracy across several activity datasets. Another line of work applies LUPI to affective computing, focusing on the

challenge of transferring models trained in the lab to real-world settings. Makantasis et al. [24] introduced the use of privileged information to bridge this gap. In their framework, high-quality multimodal signals available in controlled lab settings (e.g., audio, facial features, and physiological measures such as ECG and EDA) were treated as privileged information, while raw video frames were considered the only modality available "in the wild". They showed that performance could approach that of full multimodal models, even in noisy, uncontrolled conditions. Wang et al. [41] also used LUPI in emotion recognition, where EEG signals and video features were treated as complementary modalities: each served as privileged information for improving the other task. This work illustrated how LUPI can exploit correlations across modalities to enhance models when one modality is unavailable at test time. In the education domain, Zhao et al. [44] explored LUPI for graduate admissions prediction. They proposed S3VM+, which combined semi-supervised learning with LUPI to handle biases in committee decisions across years and to exploit large amounts of unlabeled application data. By treating yearly committee differences as privileged information, their approach outperformed standard baselines in identifying top-performing students, demonstrating LUPI's potential in educational data mining.

Our work builds on this line of research by applying the LUPI paradigm to model cognitive states in intelligent tutoring systems. Similar to the activity recognition and affective computing studies, our approach addresses the gap between rich but impractical signals and deployable features. Like Zhao et al., we operate in an educational context, but instead of admissions, we focus on modeling fine-grained cognitive states during problem solving.

2.3 Rule Learning

Inductive reasoning plays a central role in learning. It involves observing instances of a phenomenon, identifying patterns and relationships among them, and forming general rules that can be applied to new situations. The sequence of steps in this process is often described as the phases of rule learning. In cognitive science, these phases have traditionally been examined through variations of the rule attainment task [4, 7]. Such tasks are designed to capture three key phases of rule learning: rule search, rule discovery, and rule following. Typically, participants respond to a series of stimuli, indicating whether they believe the stimuli follow a rule or appear random. For example, in one version, learners see sequences of numbers that conform to a simple mathematical pattern (e.g., +2 leading to 32, 34, 36...) [20]. In another, they view numbered circles where the position of a blue circle shifts according to an underlying rule [5]. Across these tasks, specific behavioral markers make it possible to identify rule learning phases independently of the exact stimuli. This offers a standardized framework for analyzing learning processes across contexts.

Building on this tradition, our study adopts an extended set of five rule learning phases as the formalization of cognitive states (Table 1). These phases reflect how the constructs originally studied in abstract tasks translate into real-world educational problem solving:

Rule Search: Segments where learners express uncertainty or speculate without confidence about how to proceed.

Rule Discovery: Segments where learners suddenly recognize a useful principle or pattern that helps solve the problem.

Rule Following: Segments where learners apply a correct rule confidently and without hesitation.

Rule Violation: Segments where learners attempt to apply a previously correct rule but make a slip or error.

Follow Wrong: Segments where learners confidently apply a rule they believe is correct, but it reflects a misconception.

While most prior work has focused on abstract laboratory tasks, these phases have also been shown to manifest in real-world educational problem solving [37, 33]. In this study, we adopt the phases of rule learning as our formalization of cognitive states. This framing allows us to capture how learners progress from uncertainty to understanding and application. Higher-level abstractions, such as knowledge components or skills, are useful for structuring instruction but often too coarse to capture the nuanced, moment-to-moment shifts that occur during problem solving. In contrast, rule learning phases parallel these abstractions while making visible more subtle states that are otherwise difficult to define or detect. At the same time, the phases are sufficiently well-defined in cognitive science to provide a stable target for modeling.

3. LEARNING TASK DESIGN

Our study was conducted using the ASSISTments platform, an online learning environment that that supports the creation of custom problems, interactive scaffolds, and adaptive feedback. [18]. We authored 9 probability problems in the platform. Each problem in our task included multiple probability rules, which corresponded to the underlying skills or concepts required for successful problem solving. The rules covered in our problem set were: 1) identifying the number of favorable outcomes, 2) identifying the number of possible outcomes, 3) calculating probability of an event, 4) finding the probability of only one event when two events can occur together, 5) finding the probability of either of the two events happening but not both, 6) finding the conditional probability of an event, and 7) finding the probability of dependent events. Students were given access to on-demand scaffolding that allows them to break down problems into subproblems as needed (see Figure 2). Each scaffolded subproblem was associated with a single probability rule only. In addition to requesting scaffolds, students could also ask for a hint or reveal the answer if they were completely stuck.

To capture students' cognitive states throughout the learning process, we introduced a knowledge indication panel that prompts learners to self-report their current rule learning phase. Students respond to this panel whenever a new problem or scaffold appears on screen, before they can proceed with solving (see Figure 1). Their choices reflect phases such as "I know how to solve this problem" or "I don't know how to solve this problem" to initially label students as being in a rule search or rule following state.

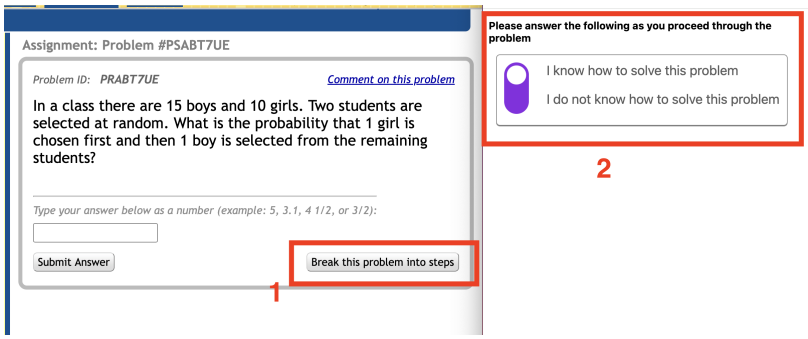

Figure 1: Screenshot of a sample problem. 1: Participants ask to divide the problem into smaller steps by clicking on this button. 2: The knowledge indication panel. Participants need to choose one of the two states on the toggle to answer the current problem on the screen.

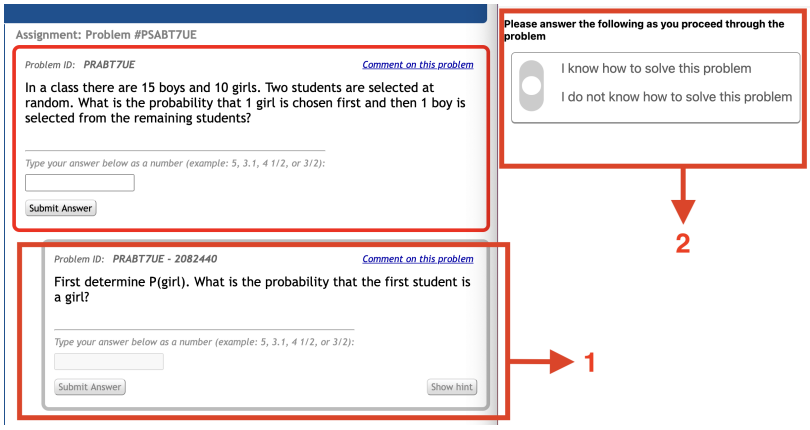

Figure 2: A sample problem showing how scaffolding is provided. 1: Once the participant clicks on the "Break this problem into steps" button shown in Figure 1, the first substep of the problem unfolds. 2: Participants continue to respond to the toggle to indicate their knowledge on the current problem for the substeps of the problem as well. For each new problem shown on the screen (either a main problem or a substep), the toggle is reset and the current problem is disabled until the participant switches the toggle.

In cases where a student's problem-solving response contradicts their indicated knowledge state (e.g., incorrect answer despite claiming to know how to solve the problem), the system triggers additional prompts to refine our understanding of their learning status. These follow-up questions help disambiguate whether the student was having a misconception (follow wrong state), was just making a guess (rule search state), made a simple mistake like a typo or miscalculation (rule violation state), or encountering a different kind of difficulty (Figure 3).

4. DATASET

4.1 Experimental Procedures

42 university students completed a combination of problem solving tasks and a rule learning task. All participants gave their informed consent prior to their inclusion and received course credit. They agreed to their audio and visual information being recorded and the collected data was de-identified prior to analysis. All study procedures were reviewed and approved by the university's Institutional Review Board. Participants began the experiment by solving a set of probability problems using ASSISTments. Initially, they were introduced to a practice set of problems to familiarize themselves with the platform. After completing the practice problems, participants proceeded to the pretest, which included 7 probability questions designed to be completed within 15 minutes. Upon completion of the pre-test, participants engaged in the rule learning task. Participants were instructed on how they could access the on-demand scaffolding by clicking on "Break This Problem Into Steps" button as well as how to use the right hand panel to indicate whether they knew how to solve the problem. After the practice, participants proceeded to solve 9 probability problems that were designed to be completed within 20 minutes using ASSISTments. They were allowed to use pen, paper, and a calculator. They were instructed to think aloud while solving the problems. The final phase involved a post-test consisting of 7 problems similar to those in the pre-test.

We collected a multimodal dataset during a structured problem solving task in the ASSISTments online tutoring system. The dataset includes behavioral interaction logs, verbal think-aloud data, and screen recordings of participants' sessions.

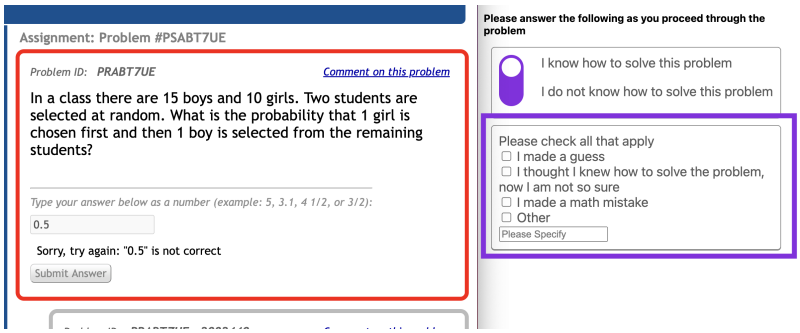

Figure 3: If the participant claims to know how to solve the current problem but provides an incorrect response or asks for scaffolding, another panel with additional options for the knowledge indication (highlighted in purple) unfolds to clarify the reason for the incorrect answer or the help request.

4.2 Behavioral Log Data

As participants interacted with the problems, we recorded detailed behavioral logs. These included the current action the participant was performing on the ASSISTments platform (submitting an answer, requesting a hint, requesting to break the problem into steps, or revealing the solution), correctness of the participants' answers to the problems if the action was an answer attempt, the items participants click on the knowledge indication panel, and timestamps of each action. The resulting dataset contains 2942 rows, with each row representing an action taken by a specific participant during the session.

4.3 Verbal Think-Aloud Data

During the task, students were asked to think aloud, verbalizing their reasoning as they worked through each problem. These verbalizations were recorded and subsequently transcribed to produce sentence-level textual data aligned with the students' actions. The transcriptions capture cognitive and metacognitive insights, such as moments of uncertainty, strategic decisions, and explanations of problem-solving steps.

4.4 Observation Notes from Screen Recordings

In addition to verbal data, we collected screen recordings of each session. These recordings were reviewed by trained coders to generate written descriptions of student actions, particularly for cases where system logs lacked sufficient context. These descriptions include observations such as hesitation before submitting an answer, switching between problem elements, or interpreting problem prompts. When combined with the think-aloud transcripts, these descriptions help contextualize the behavioral trace with higher granularity.

4.5 Labeling Cognitive States

To label cognitive states, we used a hybrid annotation approach based on both self-report data and manual coding. As mentioned in Section 3, Students were asked to complete a knowledge indication panel prior to solving each problem or scaffolded subproblem. This panel prompted them to indicate their perceived level of knowledge about the underlying rule, providing a continuous stream of self-reported rule learning states.

In cases where students provided verbal think-alouds aligned with specific actions, we used these transcriptions, along with the screen-recorded behaviors, to refine the state labels. Annotation was guided by a structured coding scheme for rule learning phases adapted from Unal et al. [33] (see Table 1), allowing coders to disambiguate ambiguous or inconsistent self-reports based on verbal evidence.

On top of the five rule learning states described above, we also observed a few instances of gaming the system in the screen recordings. Following Baker et al. [1], we flagged behaviors such as rapidly clicking through hints, repeatedly guessing until correct, or otherwise exploiting system feedback. These cases were coded but excluded from analysis, as gaming reflects disengagement rather than the cognitive processes underlying rule learning.

To ensure the reliability of our coding scheme, two coders independently annotated 20% of the dataset. Interrater agreement was assessed using Cohen's kappa, yielding a value of 0.84. Frequency of each label is presented in Table 2.

5. METHOD

We implemented a LUPI framework using knowledge distillation which has become one of the standard ways for training models with information that is only available at learning time [22]. In our setup, different "teacher" models are trained with both behavioral features from interaction logs and privileged features from either student think-alouds or observation notes from screen recordings or a combination of both privileged data sources. The teacher models' outputs are then used to guide a "student" model that only has access to behavioral features (see Section 5.2for more details). This design allows the student models to benefit from the richer representations learned by their teachers, while remaining deployable in real-world settings where privileged features are not available.

5.1 Feature Representation

In this modeling scheme, we have 2 sets of features. The first set is regular features that are extracted from student interaction logs within the ASSISTments platform. These features reflect observable student behavior and are available for real-time inference. Our second feature set is called the privileged feature set. Privileged features consisted of

Table 1: Coding Scheme Labels and Descriptions.

Label	Description	Example
Rule Search	Segments where learners express uncertainty or lack of knowledge about how to proceed. They may be speculating, experimenting, or trying different approaches without confidence.	"I'm not sure if this is right... maybe I should divide these numbers first and see what happens."
Rule Discovery	Segments where the learner suddenly recognizes a useful pattern or principle that helps solve the problem.	"Wait, I see now—we need to subtract the overlapping part from the total."
Rule Following	Segments where the learner applies a correct rule with confidence, explaining their reasoning clearly and arriving at an answer without hesitation.	"Since the events are independent, I just multiply 3/10 by 2/5 to get 6/50."
Rule Violation	Segments where the learner attempts to apply a previously correct rule but makes a mistake, often due to a slip or calculation error.	"Oops, I added those fractions and got 7/12... oh, I should have found a common denominator first."
Follow Wrong	A case where the learner confidently applies a rule they believe to be correct, but it is actually a misconception. They consistently follow the wrong logic.	"To find the total probability, we always add the numbers—so 0.3 plus 0.6 gives 0.9." (when multiplication is required).

Table 2: Frequency of cognitive states in the dataset.

Follow Wrong	Rule Discovery	Rule Following	Rule Search	Rule Violation
259	446	1248	898	91

verbal thinkaloud data, in which students articulated their reasoning while solving problems, and post-hoc observation notes transcribed from screen recordings. See Table 3 for the full list of features and their descriptions.

Verbal data streams were encoded using the all-MiniLM-L6-v2, a Sentence Transformer model that maps sentences to a 384 dimensional dense vector space to produce dense vector embeddings [32]. For instances where no think-aloud or observation note was available, we inserted a special "non textual" tag to mark the absence of verbal data.

5.2 Models & Training

The training pipeline involves two types of models: a teacher model trained with both behavioral and privileged features, and a student model trained solely on behavioral features using soft labels generated by the teacher. The idea is that the teacher, having access to richer information that privileged features provide, produces a probability distribution over the labels rather than a single hard label. The student model is then trained on this distribution instead of hard one-hot targets. Because the teacher's output reflects how it weighs similarities between classes, for example, assigning probability mass to both Rule Search and Follow Wrong states when the evidence is ambiguous, the student model gains a better sense of which states are easily confused. This provides a smoother and more informative training signal, allowing the student model to learn about subtle distinctions that are especially difficult to detect from behavioral features alone. As a result, the student can generalize more effectively to uncertain or hard-to-classify cases.

Let $x \in \mathbb{R}^d$ represent the behavioral feature vector and $x^* \in \mathbb{R}^{d^*}$ the privileged feature vector derived from participants' verbal think-alouds and/or observation notes from screen recordings. The teacher model f_T, receives the concatenated input $x_{full} = [x, x^*] \in \mathbb{R}^{d+d^*}$ and produces logits $z_T = f_T(x_{full}) \in \mathbb{R}^k$ where k is the number of cognitive states. The teacher is trained to minimize the standard cross-entropy loss:

$$\mathcal{L}\text{CE} = -\sum i = 1^K y_i \log\left(\text{softmax}(\mathbf{z}_T)_i\right) \tag{1}$$

where $y \in \{0,1\}^K$ is the one-hot encoded ground truth label.

For distillation, we applied temperature scaling to soften the teacher's output distribution. The softened probabilities are defined as:

$$p_T^{(i)} = \frac{\exp(z_T^{(i)}/T)}{\sum_{j=1}^K \exp(z_T^{(j)}/T)} \tag{2}$$

where $T > 1$ is the temperature parameter. Higher temperatures produce smoother distributions, providing the student with more informative gradients.

The student model f_S is trained on behavioral features x and outputs logits $\mathbf{z}_S = f_S(x)$. Its probability distribution with temperature scaling is given by:

$$p_S^{(i)} = \frac{\exp(z_S^{(i)}/T)}{\sum_{j=1}^K \exp(z_S^{(j)}/T)} \tag{3}$$

The student is optimized using a hybrid loss that combines cross-entropy with ground-truth labels and the KL diver-

Table 3: Regular and privileged features and their explanations.

Space	Feature	Description
x	Action	The type of the action on the current problem. Possible action types are answer attempts, hint or scaffolding requests, self reflection actions on the knowledge indication prompt, and next-button clicks.
	FirstAction	Whether the type of the first action on the current problem was an answer attempt or hint request.
	Rule	The rules associated with the current problem will be represented with a 7-dimensional vector (for the 7 distinct rules in our problem set). Each problem is tagged with 1 to 3 rules.
	TimeOnProblem	Total time spent on the current problem measured in milliseconds.
	FirstRT	First response time to the current problem measured in millisecond.
	IsMainProblem	Whether the current problem is a main problem or a sub-problem.
	AttemptCount	Number of attempts on the current problem.
	NumRule	A 7-dimensional vector representing the cumulative count of exposures to each rule up to the current problem.
	RollingMeanTime	The rolling mean of the time spent on previous NumRule problem steps for each rule that is associated with the current problem.
	SuccessRate	Proportion of correctly solved steps in the previous NumRule steps for each rule that is associated with the current problem.
${x_1}^*$	Verbal thinkalouds	Sentences in the transcriptions of student think-alouds were represented with dense sentence embeddings.
${x_2}^*$	Observation notes	Verbal descriptions of students' actions as seen on the screen recordings were represented using the same methods as we did for ${x_1}^*$.

gence with the teacher's soft labels:

$$\mathcal{L} = \alpha \mathcal{L}_{\text{CE}}(y, \text{softmax}(\mathbf{z}S)) + (1-\alpha)T^2 \mathcal{L}\text{KD}(p_T, p_S) \quad (4)$$

where

$$\mathcal{L}\text{KD}(p_T, p_S) = \sum i = 1^K p_T^{(i)} \log\left(\frac{p_T^{(i)}}{p_S^{(i)}}\right). \quad (5)$$

Here, $\alpha \in [0,1]$ controls the balance between matching the hard ground-truth labels and distilling knowledge from the teacher's softened predictions. The T^2 factor accounts for the scaling effect of the temperature on gradients.

Both teacher and student models used the same feedforward neural network architecture with two hidden layers. Hidden layers had 128 units in teacher model and 64 units in the student model. Each hidden layer used ReLU activation functions and batch normalization. The output layer used a softmax activation to produce probability distributions over the cognitive states. Models were trained using the Adam optimizer with a learning rate of 0.001 , batch size 32, and trained for 50 epochs. To select these settings, we performed a grid search over key hyperparameters, including learning rates $\{1e-2, 1e-3, 1e-4\}$, hidden layer sizes $\{64, 128, 256\}$, batch sizes $\{16, 32, 64\}$, temperature values $\{1, 2, 4, 8\}$, and hybrid loss weights $\alpha \in \{0.25, 0.5, 0.75\}$. The final configuration was chosen based on average F1 scores across folds on the validation set.

Because observation notes were produced by researchers, they were consistently high-quality and did not require further stratification. In contrast, think-alouds varied in quality so we categorized participants' think-aloud data into three groups to account for this variability. Participants who consistently articulated their reasoning and problem-solving strategies were classified as high-quality think-aloud participants ($n = 18$). Those who spoke but primarily read the problem text aloud or stated answers without reflecting on their reasoning were labeled as low-quality think-aloud participants ($n = 17$). Finally, participants who remained silent throughout were assigned to the silent group ($n = 7$). For model training, we stratified participants across these three groups when creating training and validation splits to ensure balanced representation. We used 5-fold cross validation at the participant level. We randomly oversampled participants who provided high quality think-alouds in the training folds to make sure that teacher models were exposed to richer privileged features and to strengthen the supervision signal for the student (LUPI) models. No data from the same participant appeared in both training and validation sets within a fold.

For evaluation, we computed per-class F1 scores on the validation set and. The baseline model was a behavioral-only network trained using cross-entropy loss with hard labels. Performance of the LUPI-trained student model was compared against this baseline and the privileged teacher to assess gains attributable to LUPI.

6. RESULTS

To evaluate the impact of incorporating privileged information during training, we compare performance of seven models using average F1 scores over folds. All models were trained and evaluated on the same participant-level cross-validation splits to ensure comparability. The teacher models differed in the privileged features (behavioral features were available to all models) they were given during training:

Teacher-Full had access to both think-alouds and observation notes, *Teacher-TA* had only think-alouds, and *Teacher-Obs* had only observation data. Each teacher produced soft labels (class probability distributions), which were then used to train the corresponding student (LUPI) models: *LUPI-Full*, *LUPI-TA*, and *LUPI-Obs*, that relied exclusively on behavioral features. In this setup, the student models did not differ in the features they used, but in the type of labels they were trained using: they learned from soft label distributions distilled from their respective teachers. Finally, we trained a baseline behavioral-only model using hard labels, without access to any privileged features or soft targets from a teacher.

Because evaluation was conducted using 5-fold participant-level cross validation on a relatively small dataset, we focus on the consistency and magnitude of observed performance trends rather than formal statistical significance testing. We first examined the overall performance of each model (Figure 4). The teacher models outperformed both the baseline and the LUPI models with *Teacher-Obs* achieving the highest average F1 score. This indicates that observation notes from screen recordings provided the strongest supervision signal. In contrast, *Teacher-TA* lagged behind the other teacher models which suggests think-alouds were a noisier source of privileged information.

The performance gains of the LUPI models over the baseline were modestly positive even though they did not match the teacher models' performance. This is natural as the LUPI models are smaller and rely only on behavioral features at inference. Importantly, the LUPI models achieved these gains while maintaining standard errors comparable to the baseline model, suggesting that the distillation process improved performance without increasing variability across folds. These results suggest that the distillation process provides a robust representation that generalizes well to unseen data, even in the absence of privileged information.

Having established the overall performance results, we next turn to a class-wise analysis of F1 scores to better understand where different types of privileged information contributed most to model improvements. As shown in Figure 5, performance varied across cognitive states. All models achieved very high F1 scores for Rule Following (above 0.94), suggesting that once participants are consistently applying the correct rule, behavioral information alone is largely sufficient for accurate classification. In Rule Discovery, performance differences were comparatively modest, with the baseline achieving an F1 score of approximately 0.81, LUPI models ranging between 0.79-0.81, and teacher models reaching 0.83-0.84. Unlike the more difficult states, the gains from privileged information in Rule Discovery were relatively small, suggesting that behavioral features already captured much of the information needed for classification. A similar pattern was observed in Rule Search, where the baseline already performed strongly (approximately 0.86 F1). Most LUPI models remained close to baseline performance, while Teacher-Obs achieved the strongest results (approximately 0.89 F1). This suggests that privileged information still provided additional benefit in distinguishing exploratory reasoning patterns, although the improvements were less pronounced than those observed in more subtle cognitive states such as Follow Wrong and Rule Violation.

In contrast, privileged information had the strongest impact on the more subtle states. For example, in Follow Wrong, the baseline achieved an F1 of 0.78, while LUPI models improved slightly (0.79-0.80) and teacher models, particularly *Teacher-Obs* substantially higher performance (0.85). This reflects the fact that observation notes capture students' underlying strategies and misconceptions more directly than verbalizations or behavioral logs. Similarly, Rule Violation proved to be the most challenging state overall. The baseline was lowest at 0.59 but LUPI models improved to (0.68) and teacher models pushed F1 substantially higher with *Teacher-Full* at 0.82 and *Teacher-Obs* at 0.85. Interestingly, while *Teacher-TA* did not achieve comparable scores, the corresponding *LUPI-TA* model outperformed it. This can be attributed to the hybrid loss used in training, which allowed the LUPI model to balance between its teacher model's soft predictions and the direct behavioral signal. In cases where think-alouds were noisy or not informative, the LUPI model effectively "listened" more to the behavioral data, resulting in stronger generalization than its teacher.

Our results also highlight important differences between the types of privileged information used by the teacher models. Across most cognitive states, Teacher-Obs achieved the strongest or near-strongest performance, while Teacher-Full also consistently outperformed the baseline and LUPI models. This suggests that observation-based privileged information provided a particularly strong supervision signal for detecting students' cognitive states. At the same time, the competitive performance of Teacher-Full indicates that combining modalities can still provide complementary information, even if the additional think-aloud features did not always translate into higher F1 scores. When the modalities were examined separately, Teacher-Obs generally outperformed Teacher-TA. One explanation to why Teacher-Obs mostly outperformed Teacher-TA can be that the observation data was a stronger signal on its own. Even though think-alouds provided more raw data, they were often noisier, since many verbalizations are generic and occur across multiple states. For example, students may express surprise after giving an incorrect answer both when they are in a Follow Wrong phase (reflecting a deeper misconception or flawed mental model) and when they are in a Rule Violation phase (reflecting a simple slip despite otherwise correct knowledge). In contrast, observation data such as watching how students solve the problem on the calculator (on their computer screen) or sequence their inputs provides evidence of the strategies and mental models they are using. Because of this, observation features may have offered more discriminative information for distinguishing subtle differences between cognitive states.

These differences also carried over to the student models. While the gains over the baseline were more modest than those observed for the teacher models, the LUPI variants demonstrated that privileged information could still improve performance even when only behavioral features were available at inference. The effect was especially noticeable in the more challenging cognitive states, where the quality of the privileged supervision signal appeared to matter most. For example, in Follow Wrong, the Teacher-TA model per-

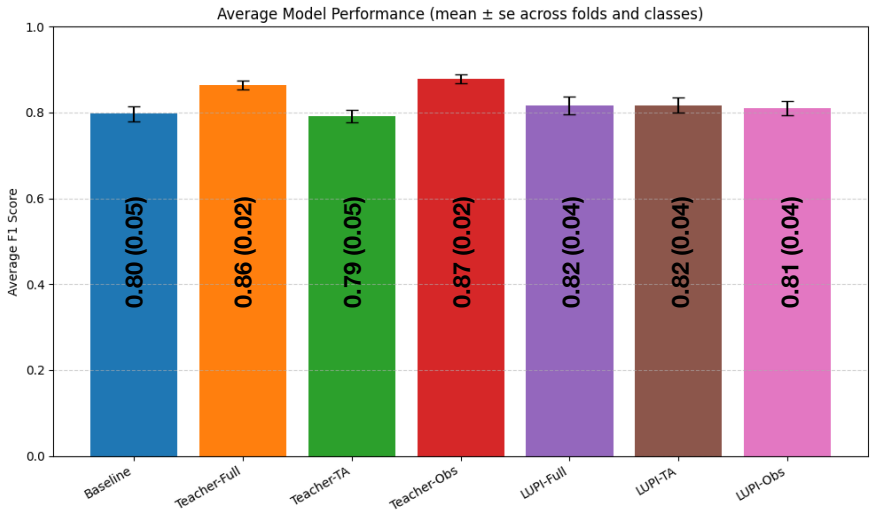

Figure 4: Comparison of Average F1 Scores and standard errors of the Models.

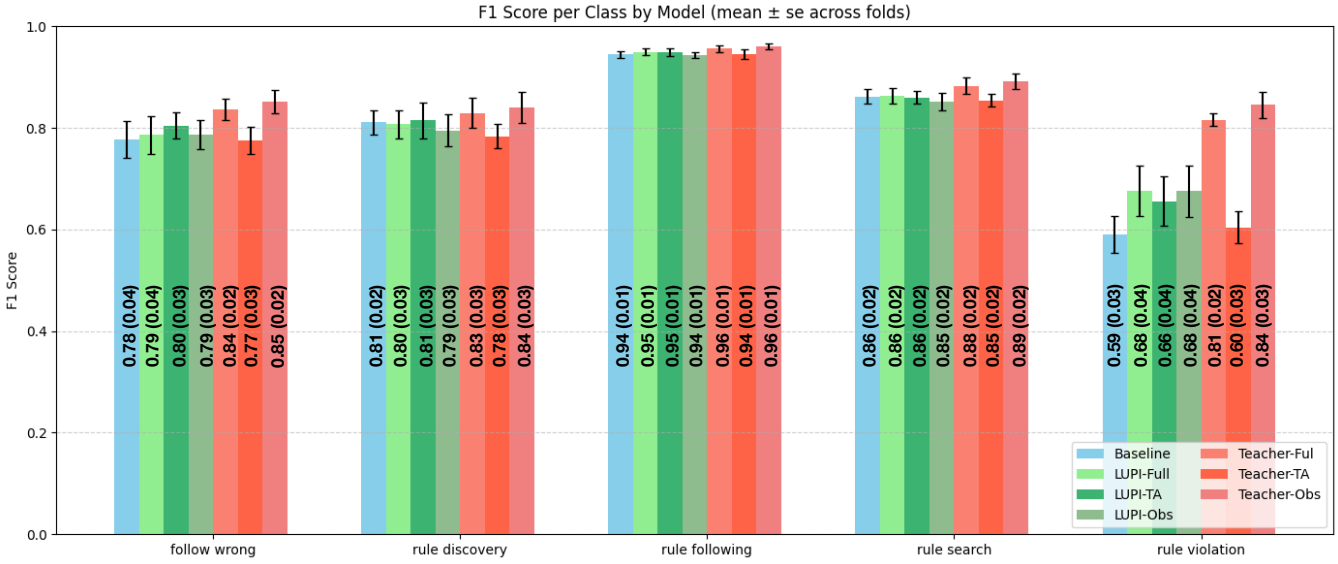

Figure 5: Mean class-wise F1 Scores and Standard Errors of the Models.

formed comparatively poorly, suggesting that think-alouds alone were often too noisy to reliably distinguish deeper misconceptions from neighboring states. However, the corresponding LUPI-TA model achieved stronger performance, likely because the hybrid distillation objective allowed it to balance between the teacher's soft predictions and the ground-truth hard labels derived from behavioral data. In this sense, the student model was able to retain the most informative aspects of the privileged signal while reducing the impact of noisy verbalizations. A similar pattern appeared in Rule Violation, the most difficult state overall. Here, observation-based privileged information proved especially valuable, as both Teacher-Obs and LUPI-Obs substantially outperformed their think-aloud counterparts. This suggests that observation data provided more discriminative cues about students' underlying strategies and slips in reasoning, while think-alouds alone were often insufficiently specific. The strong performance of LUPI-Full further indicates that combining privileged modalities can still be beneficial when the student model learns to integrate comple-

mentary supervision signals through distillation.

7. DISCUSSION

In this work, our goal was to investigate whether incorporating privileged information through a LUPI framework can improve the modeling of cognitive states in a realistic learning environment. We used the phases of rule learning as our target cognitive states, because they offer an appropriate granularity for capturing nuanced, moment-to-moment shifts in cognition that are not easily represented in higher-level abstractions such as mastery / non-mastery in traditional knowledge tracing [6] or broader stages of skill acquisition in cognitive psychology such as cognitive and associative stages [15]. We compared the performance of teacher models with access to privileged information (think-alouds and observation data), student models trained on behavioral data only, optimized using soft labels distilled from those teachers, and a baseline model trained on the same behavioral data, optimized using hard labels. Our findings showed three main patterns. First, teacher models outperformed behavioral-only baselines, demonstrating that privileged information provides valuable insight into the learning process. Second, student models trained with teacher soft labels (LUPI) consistently outperformed the baseline despite relying only on behavioral data at test time. Third, these gains were most pronounced for subtle states such as Follow Wrong and Rule Violation, which are difficult to distinguish from behavioral features alone. The results also revealed differences between modalities. Observation data often provided a stronger standalone signal than think-alouds, but the best results were achieved by combining both. The models demostrated strong generalization as all evaluations were conducted on unseen participants. The consistency of performance across folds highlights the robustness of our approach and the transfer of privileged information benefits to new learners is both reliable and effective.

Beyond predictive performance, the utility of modeling rule learning phases lies in the potential to inform feedback. By detecting nuanced states such as Follow Wrong or Rule Violation in real time, systems could provide targeted interventions that directly address misconceptions or slips without needing additional context about the specific problem, rather than treating all errors as equivalent. Similarly, identifying transitions into Rule Discovery opens opportunities for reflective prompts that help consolidate new understanding. This phase-level precision creates possibilities for adaptive support that is both more timely and more tailored than what is achievable with traditional correctness-based models.

Despite these promising results, our work has several limitations. First, the sample size was modest, which is common in this line of research [11]. While participant-level cross-validation mitigated the risk of overfitting, larger studies will be needed to validate the robustness of our findings. Second, while observation data proved valuable, it was generated through researcher coding of screen recordings, which may limit scalability. Future work should explore automated extraction of similar data. Third, think-aloud data were highly variable in quality, consistent with prior findings that verbal protocols can range from deeply reflective to surface-level or uninformative. Although we stratified participants by think-aloud quality in our cross-validation splits, the variability highlights the need for methods to reduce noise.

Our research can lead to several future directions. Firstly, while this work focused on modeling rule learning phases, the proposed learning framework is not limited to this context. In principle, any type of privileged information that provides deeper access to students' cognitive or affective states could be incorporated at training time. For example, sensor-based modalities such as facial expressions, posture, or physiological signals have long been shown to capture affective dynamics relevant for learning [16], but their reliance on specialized equipment limits classroom deployment. Sensor-free affect detectors developed using behavioral proxies such as timing patterns, hint use, or keystroke dynamics already aim to approximate such states [9]. A promising direction for future work is to train LUPI models on multimodal or sensor-based privileged signals, while using sensor-free behavioral detectors as the deployable counterpart. This would allow researchers to take advantage of the richness of lab-collected affective data while maintaining scalability in real-world systems. A natural extension is to neuroscience, where privileged signals such provide direct access to neural mechanisms that underlie rule learning and other higher-order cognitive processes. Prior research has shown that distinct phases of rule learning are associated with signature patterns of brain activation, including shifts between prefrontal and parietal regions as learners move from rule search to rule following [20]. While such data are difficult to collect outside of controlled laboratory environments, they offer a uniquely fine-grained and objective window into cognition. A LUPI framework could allow us to leverage these neural signatures as privileged information during training, improving the ability of deployable models to infer subtle cognitive states in real time from behavioral logs alone.

Furthermore, an additional line of inquiry is to explore participant level training, where models are individualized based on richer data collected from each learner. Prior work in multimodal learning analytics and neuroscience has shown that such approaches can improve classification accuracy when sufficient data per participant is available [23]. While our study was not designed at that level of granularity, this type of approach could be especially valuable in settings with larger datasets per learner.

Finally, another promising line of research lies in improving the quality of verbal data used as privileged information. Thinkalouds are valuable for revealing reasoning processes, but as observed in our study and others [45], their quality varies widely across learners. Large language models (LLMs) have recently shown promise in evaluating, coding, and even scaffolding verbal explanations in educational contexts [43]. Leveraging LLM based evaluation could help filter noisy or surface level thinkalouds to enhance the reliability of verbal data as privileged information, and even provide real time feedback to learners as they articulate their reasoning. These directions point to a broader role for LUPI in learner modeling, serving as a bridge between modalities that are rich but impractical at scale and the behavioral data streams that are readily available in classrooms and tutoring systems.

ABSTRACT

Video-LLMs hold significant potential for analyzing classroom dynamics to inform pedagogy and drive educational innovation. There is an urgent need to assess the capability of Video-LLMs in educational applications to identify their potential and limitations. Existing educational evaluation datasets often suffer from three major shortcomings: reliance on small-scale, single-label human annotations; a focus on unimodal analysis; and the absence of granular annotations required for multi-step reasoning. To address these gaps, we first introduce an efficient Human-LLM collaborative pipeline for high-quality multimodal annotation. We then propose **MTBU-Bench**, a comprehensive multimodal benchmark designed to assess teacher behavior understanding. It comprises over 300 classroom scenarios across 15 K-12 and higher education disciplines, organized into four evaluation tasks: Action Recognition, Temporal Boundary Extraction, Spatial Localization, and Behavioral Description. Extensive evaluations of twelve mainstream Video-LLMs reveal critical shortcomings in fine-grained temporal understanding, specifically in the precise localization of action boundaries and the discrimination of similar behaviors. Our benchmark and findings provide a foundation for the targeted development and application of Video-LLMs in educational research. The code and dataset are publicly available at our project homepage: `https://github.com/271213/MTBU-Bench`.

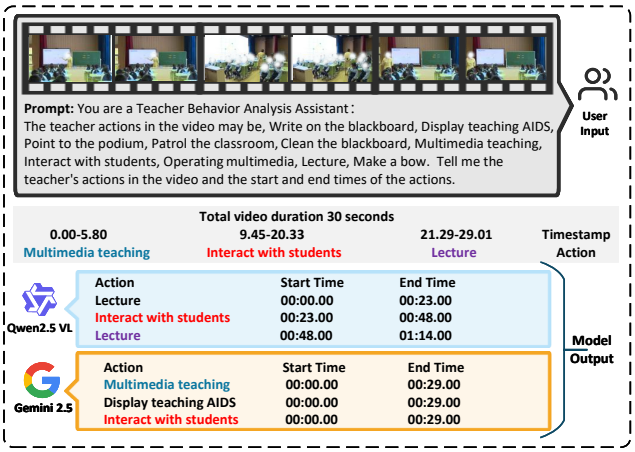

Figure 1: An example of the current Video-LLMs limitation in temporal boundary extraction from videos.

1. INTRODUCTION

In recent years, Video large language models (Video-LLMs), which integrate visual encoders with large-scale pre-trained language models, have demonstrated remarkable performance in video understanding tasks [17, 19, 16]. These models are capable of jointly processing spatiotemporal visual features and semantic reasoning tasks, unlocking new possibilities for comprehending complex scenes [44, 14]. Among the domains empowered by such advancements, education stands out as a critical application area where video understanding facilitates teaching assessment and instructional strategy optimization [45]. In particular, through analyzing instructional actions, spatial positions, and interaction targets within authentic classroom environments, teacher behavior understanding not only provides an objective reflection of teaching effectiveness but also fosters pedagogical self-reflection and offers interpretable insights for professional development [32, 1]. Consequently, evaluating the reasoning capabilities of Video-LLMs in educational settings has become an essential research challenge.

Mainstream Video-LLMs typically rely on static image-based representations, extracting keyframes from input videos to conduct semantic modeling and action recognition [9, 40]. However, such keyframe-driven paradigms pose inherent limitations when applied to fine-grained analysis of teacher behavior in authentic classroom settings [37]. Specifically, the omission of continuous temporal information compromises the model's ability to accurately delineate action boundaries, often leading to temporal ambiguity as shown in Figure 1. Moreover, for semantically similar behaviors such as "write on the blackboard" versus "clean the blackboard" existing models still struggle with disambiguation, resulting in frequent semantic confusion. These challenges significantly hinder the effectiveness of current Video-LLMs in educational behavior understanding tasks.

Although prior studies have explored video understanding tasks within educational contexts [29, 35], existing benchmarks remain inadequate for systematically evaluating the reasoning capabilities of Video-LLMs. This inadequacy stems from three primary limitations: 1) Current datasets predominantly rely on manually annotated, single teacher action labels, which are costly to produce and prone to annotator bias. They are typically confined to small-scale instructional videos [37, 23]; 2) Existing research is largely limited to unimodal video analysis [11, 12], failing to leverage the complementary strengths of multimodal data, thereby constraining the comprehension of rich classroom interaction dynamics; 3) Present benchmarks tend to focus on coarse, single-label descriptions of teacher action [6], lacking fine-grained annotations of behavior, interaction targets, and contextual features, which are essential for aligning with the multi-step reasoning processes of Video-LLMs.

To address the aforementioned challenges, we propose **MTBU-Bench**, the first multimodal evaluation benchmark tailored for assessing Video-LLMs on teacher behavior understanding tasks. **MTBU-Bench** spans 15 academic disciplines (Math, Physics, Biology, Chemistry, Science, Geography, History, Chinese, English, Music; Higher education: Medicine, Political - History, Engineering, Liberal Arts, Natural Sciences.) across K-12 and higher education, comprising over 500 complete, authentic classroom videos from more than 300 distinct teaching scenarios. As illustrated in Figure 2, each instance includes multimodal representations of teacher behavior along with five annotated dimensions: behavior category, spatial location, interaction target, video description, and Question–answer (QA) pairs. To ensure both annotation efficiency and multimodal consistency, we introduce a multi-stage Human–LLM collaborative annotation pipeline. This workflow integrates expert annotations, senior expert validation, and LLM-assisted behavioral description generation. Based on this, we conduct a comprehensive evaluation of ten mainstream Video-LLMs (e.g., GPT-4V, Gemini 2.5 Pro), focusing on four core tasks: teacher action recognition, teacher behavior temporal boundary extraction, teacher behavior spatial localization, and teacher behavior description. Experimental results reveal notable limitations in current Video-LLMs, particularly in recognizing similar behaviors, aligning interaction targets, and modeling environmental context.

2. RELATED WORKS

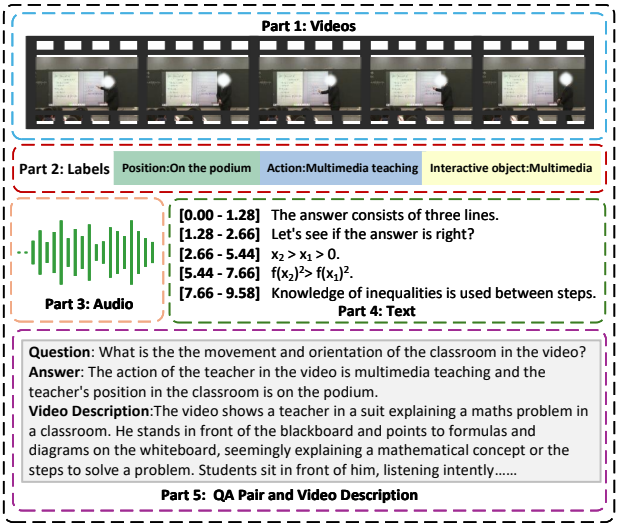

Figure 2: Data composition of MTBU-Bench.

2.1 Video Understanding Dataset

Video understanding aims to automatically generate natural language descriptions of key events, human actions, and scene contexts within videos, and has been widely applied in educational analysis, video retrieval, and supplementary instruction [27, 7, 38]. With the rapid development of multimodal understanding and generative models, video captioning has evolved from single-sentence summaries to structured, hierarchical, and fine-grained representations. The MiraData dataset, employing the GPT-4V model to generate detailed descriptions from six distinct perspectives [24]. The YouCookII dataset focuses on instructional videos in cooking scenarios, providing temporal boundaries and English descriptions for each procedural step [49]. The ViTT dataset further extends to multi-domain instructional videos, offering short tags averaging three words per segment [21]. To pursue higher-quality and more detailed long-form descriptions, the Koala-36M dataset provides 36 million filtered video clips with detailed, structured captions averaging 200 words [42]. Recent research has also pushed into grounding these descriptions, with ViCaS linking captions to pixel-level segmentation masks [3], and HD-EPIC further grounding fine-grained actions and objects within 3D digital twins from an egocentric perspective [34].

2.2 Datasets for Teacher Analysis

Compared to general video datasets, educational video data place greater emphasis on multimodal alignment, authentic instructional context, and structured annotations. The EduNet dataset, encompassing 20 categories of teacher and student behaviors across 7,851 video clips [37]. TBU is a multi-task teacher behavior dataset that includes three kinds of labels across 200 classroom videos [6]. TCDA focuses on teacher dress code assessment containing 11,879 annotated images with 25 attribute categories teacher dress [12]. TAQR is the benchmark dataset dedicated to teacher action quality ranking, covering four core instructional behaviors 1,200 video clips [11]. However, all of these datasets are limited to manually annotated unimodal data and lack multi-

Table 1: Comparison of MTBU-Bench with existing teacher behavior datasets.

Dataset	Modalities	Scale	Subject	Ed. Stage	Open Source	Tasks
TAR [23]	Visual	13,288 clips	N/A	Vocational	✗	Action Recognition

dimensional fine-grained video descriptions, making them insufficient for directly evaluating the reasoning capabilities of Video-LLMs. A detailed comparison of MTBU-Bench with these existing teacher behavior datasets is summarized in Table 1.

2.3 Evaluation of Video-LLMs

With the development of Video-LLMs, a series of evaluation benchmarks has also emerged [47, 48], each with a distinct focus. Video-MME [15] aims for comprehensive evaluation, covering diverse video types, durations from 11 seconds to 1 hour. ALLVB [39] concentrates on ultra-long video understanding, using videos averaging nearly two hours to assess long-sequence modeling capabilities [17]. Other benchmarks focus on more fine-grained abilities[28], such as MotionBench [18], which specifically evaluates the understanding of fine-grained motion. However, these general-purpose benchmarks, despite their advancements in comprehensiveness, duration, and granularity, do not address the specific needs of educational scenarios, such as the fine-grained understanding of teacher behavior[2, 30]. **MTBU-Bench** is the first comprehensive multimodal benchmark designed to fill the crucial gap of evaluating Video-LLMs understanding of teacher multimodal behavior.

3. MTBU-BENCH

In this section, we introduce MTBU-Bench, the first comprehensive multimodal benchmark tailored for assessing Video-LLMs on teacher behavior understanding tasks. Spanning 15 academic disciplines across K-12 and higher education, the dataset comprises over 500 complete, authentic classroom videos from more than 300 distinct teaching scenarios. To ensure annotation quality and multimodal consistency, we construct the benchmark through a Human-LLM Collaborative Annotation pipeline that effectively integrates expert knowledge with automated generation capabilities. We organize the dataset into four core task subsets: Multimodal Teacher Action Recognition, Teacher Behavior Temporal Boundary Extraction, Teacher Behavior Spatial Localization, and Teacher Behavior Description, designed to systematically evaluate the fine-grained perception and reasoning capabilities of large models in complex educational environments.

3.1 Data Construction Workflow

As shown in Figure 3, we propose a Human-LLM Collaborative Annotation pipeline to construct **MTBU-Bench**, including video collection, Annotation System Construction, data segmentation and annotation, quality assurance, multimodal extraction and alignment, behavior description generation, question-answer pair generation, description and QA Pair verification.

Video Collection. We collect 500 complete classroom teaching videos spanning multiple educational levels from K-12 to higher education. It covers 15 academic subjects and includes both public lectures and competition-based lessons. The recorded classroom scenarios exhibit diverse camera perspectives, varied instructional formats, and heterogeneous spatial layouts, totaling more than 300 distinct teaching environments. These videos faithfully capture pedagogical characteristics, teacher behaviors, and classroom interaction patterns across different educational stages, offering strong representativeness and practical applicability for multimodal educational research.

Annotation System Construction. To support multimodal reasoning and enable comprehensive modeling of teacher behaviors, we design a structured annotation system composed of four key dimensions. First, we define a set of ten core instructional actions based on their high frequency and semantic distinctiveness in real-world classrooms. Second, we annotate the spatial position of the teacher during action execution to provide grounding for spatiotemporal localization. Third, we annotate the primary interaction object to reflect communicative targets and teaching intent. Finally, we generate structured natural language descriptions that integrate visual, auditory, and contextual cues, offering rich semantic supervision for downstream Video-LLMs. This four-dimensional annotation schema ensures interpretability, consistency, and task alignment across the benchmark.

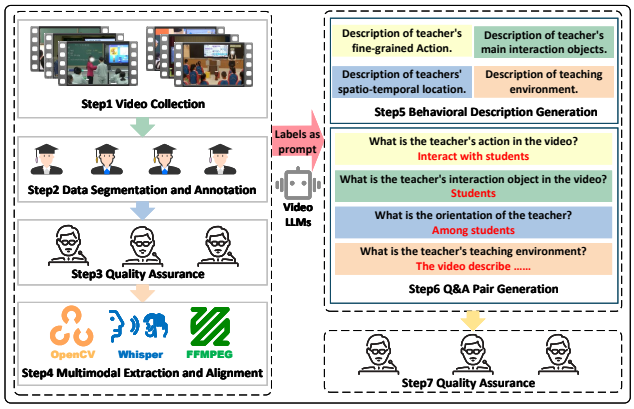

Figure 3: Construction pipeline of MTBU-Bench.

Data Segmentation and Annotation. To construct a multimodal dataset tailored for teacher behavior understanding, we adopt behavior segments as the fundamental annotation unit. Raw instructional videos are temporally segmented and annotated to ensure that each segment exhibits content completeness, clear temporal boundaries, and semantic consistency with respect to the behavior it represents. The segmentation is conducted using videoManager, with each segment corresponding to the full execution of a distinct teaching action. The start time is defined by the onset of an observable behavioral cue, while the end time is marked by the action's completion or transition into the next behavior. The granularity of segmentation follows the principle of units of semantic behavior, balancing multimodal observability with the pedagogical coherence of instructional behaviors [25].

To ensure the high quality, accuracy, and pedagogical domain fidelity of the MTBU-Bench dataset, the annotation process was driven by a highly qualified, cross-disciplinary team. This team consisted of one primary researcher, three experienced frontline teachers (each with over 10 years of classroom teaching experience), and four graduate students (two specializing in Education and two in Computer Science).

The annotation process followed a rigorous collaborative workflow. Initially, the primary researcher and the frontline teachers collaboratively finalized the behavior labels to ensure they accurately reflected authentic instructional dynamics. Subsequently, they conducted comprehensive training for the four graduate students. The annotators were provided with detailed annotation guidelines, which included strict label definitions, concrete annotation examples, and standardized operating procedures for the annotation tools.

During the execution phase, the annotation tasks were divided into four subsets. Rather than being separated by educational stages or subject areas, each subset encompassed content from all disciplines and educational levels. All four graduate students were jointly responsible for the data segmentation and annotation tasks across all four subsets. Each behavior instance was meticulously annotated with four key attributes: teacher action, spatial position during the action, interaction target, and start and end timestamps.

Quality Assurance. To guarantee the overall reliability of the dataset, the three frontline teachers independently conducted a Quality Assurance phase, rigorously reviewing and validating the temporal boundaries and semantic labels of the annotated clips. Furthermore, to evaluate inter-annotator agreement, a 10% data overlap was maintained across the subsets. Any discrepancies were resolved through group discussion and majority voting. The final annotation consistency was quantitatively assessed using Fleiss' Kappa, yielding a score of 0.949, which indicates a "high agreement" level [13]. This review process focuses primarily on verifying and harmonizing the temporal boundaries of annotated behaviors, and enhancing the overall consistency and scientific rigor of the dataset.

Multimodal Extraction and Alignment. We employ a suite of open-source tools including OpenCV[1], Whisper[2], and FFmpeg[3] to automate the extraction and alignment of visual, audio, and textual modalities from classroom videos. Through a timestamp-based synchronization mechanism, teacher actions in the visual stream, spoken content in the audio stream, and semantic information in the text stream are precisely aligned to form temporally consistent multimodal behavior segments. This stage ensures that each annotated teacher behavior instance maintains high consistency and semantic completeness across visual, auditory, and linguistic modalities.

Behavior Description Generation. To enhance model understanding in classroom teacher behavior recognition tasks, we construct a four-dimensional description for each annotated video segment. Each dimension is designed to complement behavior semantics from a distinct perspective, thereby improving the model's capability to recognize fine-grained instructional behaviors in complex classroom environments. Building upon high-quality annotations, we leverage the Video-LLMs to generate four types of structured natural language descriptions for each behavior clip, as detailed below:

- **Fine-grained description of teacher actions**. This dimension provides fine-grained descriptions of core instructional actions to distinguish semantically different but visually similar behaviors. For example, "clean the blackboard" and "write on the blackboard" share similar visual cues standing in front of the blackboard and using hand gestures yet their pedagogical intents diverge, often leading to misinterpretation by Video-LLMs. By documenting micro-actions (e.g., hand-raising, body-turning, or using teaching aids) and subtle temporal patterns, this dimension enhances the model's capacity to disambiguate near-identical actions and capture critical shifts in instructional orientation.
- **Spatial location of behavior execution**. This dimension captures the teacher's spatial position, which serves as a critical indicator of instructional intent. For instance, positions such as the classroom corners or the

[1]https://github.com/opencv/opencv
[2]https://github.com/openai/whisper
[3]https://github.com/FFmpeg/FFmpeg

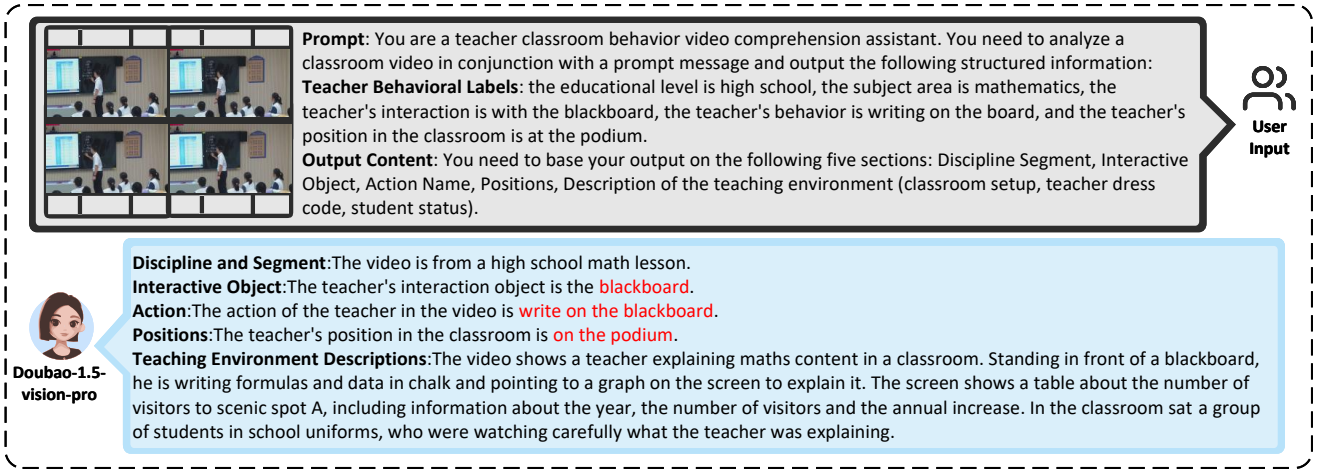

Figure 4: An example of Video-LLMs for teacher behavior description.

blackboard center correlate with specific actions like "patrol the classroom" or "lecture". Explicitly encoding spatial context enhances the model's contextual grounding and classification accuracy by leveraging the strong spatial dependencies of instructional behaviors. Ultimately, spatial location functions as a discriminative feature that significantly improves action recognition performance.

- **Primary interaction target during behavior execution**. This dimension explicitly identifies interaction targets such as students, blackboards, or multimedia devices to clarify the object associated with each instructional behavior. Distinguishing these targets is essential for interpreting pedagogical intent and serves as a primary criterion for differentiating between lecture driven actions and interactive driven actions. For instance, engaging with students signifies interactive behavior, while manipulating multimedia denotes a control action. Ultimately, these annotations support downstream tasks like pedagogical strategy analysis and classroom structure modeling.

- **Instructional environment context**. This dimension captures environmental cues such as classroom layout, teacher attire, and student status to provide essential context for interpreting instructional actions. For example, laboratory settings with lab benches often imply demonstrative actions, while traditional attire combined with a projection screen aligns with "lecture" or "multimedia teaching" scenarios. These cues are pivotal for filtering non-instructional behaviors and enhancing model precision and robustness. Ultimately, these features ensure semantic coherence in behavioral analysis and reinforce the reliability of multimodal alignment.

These structured descriptions provide rich semantic grounding for subsequent behavior understanding and multimodal evaluation tasks. Behavior description generation process is shown in Figure 4.

Question–Answer Pair Generation. Building upon the structured behavior descriptions, we further employed Video-LLMs to generate QA pairs for each classroom behavior segment. Each QA pair targets one of four key dimensions: the teacher's instructional action, spatial position, primary interaction object, and the surrounding instructional environment. The integration of QA pairs not only enriches the semantic depth of the dataset enabling models to acquire more fine-grained insights into teacher behaviors but also strengthens cross-modal alignment ability. Moreover, this QA-based design lays a high-quality foundation for downstream applications such as instructional question answering systems and fine-tuning large models for classroom behavior analysis and evaluation in educational settings [46, 36, 43].

Description and QA Pair Verification. Domain experts review the model-generated descriptions and question–answer pairs with respect to four key dimensions: instructional actions, spatial positioning, primary interaction targets, and the surrounding classroom environment.

3.2 Dataset Subset Composition

As shown in Figure 5, **MTBU-Bench** comprises four distinct subsets, each tailored to a specific evaluation objective: multimodal teacher action recognition, teacher behavior temporal boundary extraction, teacher behavior spatial localization, and teacher behavior description. These subsets are designed with a clear structural organization, comprehensive annotations, and a strong task-driven focus, making the dataset well-suited for advancing research in educational video understanding across multiple dimensions.

3.2.1 Multimodal Teacher Action Recognition Subset

Teacher Action Labels. The Multimodal Teacher Action Recognition Subset (MTAR Subset) is designed to provide standardized data for instructional action recognition, focusing on ten of the most frequently observed teacher actions in classroom settings: Write on the blackboard: The teacher uses chalk or a marker to write text, formulas, or draw dia-

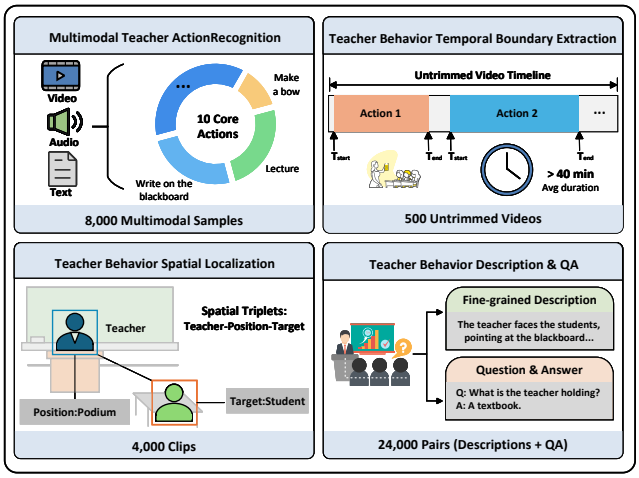

Figure 5: Statistics and task illustrations of the four subsets in MTBU-Bench.

grams on the physical blackboard or whiteboard. Clean the blackboard: The teacher uses an eraser or cloth to remove content from the physical blackboard or whiteboard. Multimedia teaching: The teacher utilizes digital platforms (e.g., presenting slides, playing videos) as the primary medium to deliver instructional content. Operating multimedia: The physical action of the teacher manipulating technological devices (e.g., typing on keyboard, clicking mouse, adjusting projector) to control the flow of digital content. Display teaching aids: The teacher physically holds up or demonstrates physical objects, models, or printed materials to the students to facilitate understanding. Interact with students: The teacher engages in direct, two-way communication with students, including asking questions, answering queries, or guiding group discussions. Lecture: The teacher delivers verbal explanations of academic concepts to the entire class, typically standing still without intense physical interactions with props or the board. Patrol the classroom: The teacher walks dynamically among the classroom to monitor progress, observe independent work, or provide localized guidance. Point to the podium: The teacher uses hand gestures or a pointer to direct students' visual attention to specific content on the blackboard or projection screen. Make a bow: A formal, ritualistic action where the teacher bows to the students, typically occurring at the very beginning or end of a lesson. [22, 26, 5].The data distribution is shown in Table 2.

This subset contains a total of 8,000 multimodal samples, covering the ten core instructional action. Each sample includes a high-quality video clip, synchronized audio, and its transcribed text, ensuring precise alignment across the three modalities. This subset is suitable for training and evaluating multimodal action recognition models and supports research directions such as cross-modal retrieval, audio-visual joint modeling, and multimodal feature fusion. It serves as foundational training data for multimodal models in educational scenarios.

3.2.2 *Teacher Behavior Temporal Boundary Extraction Subset*

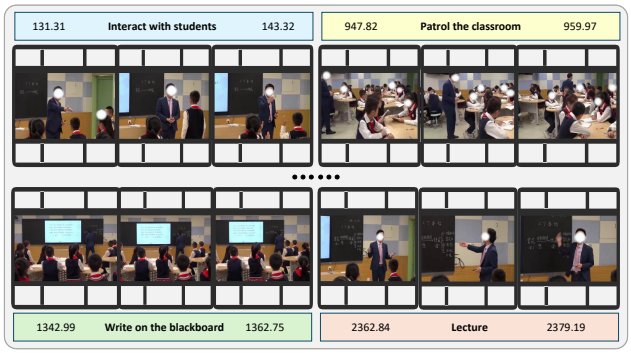

Figure 6: Examples from the Teacher Behavior Boundary Extraction Subset.

To address the bottlenecks of current Video-LLMs in long video understanding and temporal localization, we construct the Teacher Behavior Temporal Boundary Extraction Subset. Unlike most existing benchmarks that rely on short trimmed clips, this subset comprises 400 complete classroom teaching videos, with an average duration exceeding 40 minutes per session.

These untrimmed videos fully preserve the continuity and complexity of authentic instructional activities. We provide dense, frame-level annotations, precisely marking the start and end timestamps of every teacher action throughout the entire lesson. This setup presents a significant challenge for models: they are required not only to recognize specific action categories but also to precisely delineate action boundaries within a long-horizon context, thereby testing their capability to handle temporal redundancy and transition ambiguity in real-world continuous video streams. Examples from the Teacher Spatiotemporal Behavior Localization Subset are provided in Figure 6.

3.2.3 *Teacher Behavior Spatial Localization Subset*

To evaluate the fine-grained spatial reasoning capabilities of Video-LLMs within complex classroom environments, we construct the Teacher Behavior Spatial Localization Subset (TBSL Subset). To ensure the reliability of spatial reasoning evaluation, this subset consists of 4,000 high-quality short video clips carefully selected from the 8,000 clips in the MTAR subset. We strictly filtered for instances where the teacher's spatial orientation and positional information are highly discernible, and the continuous action duration exceeds 10 seconds.

Teacher Spatial Position and Interaction Target Labels. Each sample is annotated with a structured behavior triplet, comprising the teacher action, their spatial position relative to the classroom layout, and the corresponding primary interaction target. Spatial positions include being On the podium: where the teacher is located in the defined instructional zone at the front of the classroom, typically near the blackboard and main desk; Among students: where the teacher is located within the student seating area, moving through the aisles or standing next to desks; and Behind the classroom: where the teacher is positioned at the very back of the room, typically to observe the entire class's sta-

Question: What is the object of the teacher's interaction in the video?
Answer: The teacher's interaction object is the teaching AIDS.

Video Description: The video is from a high school math lesson. The action of the teacher in the video is **display teaching aids.**
The teacher's position in the classroom is **on the podium**.
The teacher's interaction object is the **teaching AIDS**.
The video shows a teacher teaching in a classroom, standing in front of a blackboard, holding a bottle of drink and explaining the lesson content to students. On the screen are the words "Renjiao A version Selective Compulsory I Chapter 3 Equations of Conic Curves" and "3.1.1 Ellipse and its Standard Equation (Lesson 1)", with the name of the teacher next to it. The students were wearing uniform green jackets and sitting at their desks, listening attentively to the lectures.

Question: The orientation information for the classroom in the video is?
Answer: the teacher's position in the classroom is from among students to behind the classroom.

Video Description: The video is from a high school math lesson.
The action of the teacher in the video is **patrol the classroom.**
The teacher's position in the classroom is **from among students to behind the classroom**.
The teacher's eyes are interacting with the **students**.
The video shows a scene inside a classroom where students wearing uniform white school uniforms sit at their desks and study carefully. A teacher walks back and forth in front of the classroom, seemingly inspecting and guiding the students. The entire classroom is simply decorated and well-lit, creating an atmosphere of focused learning.

Figure 7: Example data of Teacher Behavior Description Subset.

Table 2: Subset Data Distribution.

MTAR Subset

TBSL Subset	
Spatial positions	Number
On the podium	2,256
Among students	1,531
Behind the classroom	213
Interaction target	Number
Blackboard	1,073
Multimedia	463
Teaching aids	798
Students	1,145
Multimedia PPT	521

tus or during student-led presentations. Furthermore, primary interaction targets include the "Blackboard" for traditional physical writing surfaces; "Multimedia PPT" for digital slides or educational software interfaces displayed on a screen; "Multimedia" for hardware devices such as computers, projectors, or interactive smartboards; "Teaching aids" for physical objects, biological specimens, geometric models, or chemical apparatus; and "Students" for individual students or the class as a whole. The data distribution is shown in Table 2. These triplets provide fine-grained and semantically rich supervision for modeling spatial reasoning in instructional scenarios. The teacher's interaction target offers implicit cues regarding their spatial orientation; this correlation between interaction semantics and spatial positioning is critical for Video-LLMs to build accurate representations of instructional context.

3.2.4 Teacher Behavior Description Subset

The Teacher Behavior Description Subset is dedicated to supporting video-to-text generation and question answering tasks within educational contexts. For each behavior segment, the subset provides a detailed natural language description that encapsulates semantic elements such as the type of action, spatial location, and interaction target. To further enhance the model's reasoning capabilities in complex instructional scenarios, each description is paired with a corresponding video-based QA pair, enabling both generative and comprehension-based evaluations of multimodal language models, example data is displayed in Figure 7.

In total, the subset contains 24,000 natural language descriptions aligned with corresponding video segments, along with 24,000 QA pairs grounded in the semantic content of those segments. These 24,000 samples are directly derived from the 8,000 MTAR clips by generating three distinct descriptions and corresponding QA pairs from different semantic perspectives for each clip. Each description averages 26 words in length and captures rich semantic dimensions, including teacher actions, classroom environment, and interactive elements. This subset provides a standardized benchmark resource for fine-tuning and evaluating multimodal large models in educational scenarios.

4. EXPERIMENTS

4.1 Experimental Setup

To evaluate the fundamental capabilities of mainstream Video-LLMs on the teacher behavior understanding task, we conducted a systematic zero-shot evaluation of ten representative models, including GPT-4V, Gemini 2.5 Pro, Video-LLaVA, LLaMA 4-17B, Qwen2.5-Omni, Spark X1 (education-oriented), Grok3, Qwen-QVQ, Claude 3.5 Sonnet, and Kimi-latest. All experiments were conducted under a zero-shot inference setting without any task-specific fine-tuning or training. The evaluation was performed on the four core subtasks of **MTBU-Bench** Teacher Action Recognition, Teacher Behavior Temporal Boundary Extraction, Teacher Behavior Spatial Localization Subset , and Behavior Description, using a unified standard to ensure comparability and reproducibility of the results.

In terms of test scale, we constructed a comprehensive zero-shot evaluation dataset tailored to the specific characteristics of each task. For Teacher Action Recognition, Spatial Localization, and Behavior Description, we utilized a dataset comprising 4,000 samples, with 400 samples drawn from each of the 10 core teacher action categories. For Teacher Behavior Temporal Boundary Extraction, considering the current limitations of Video-LLMs in long-context understanding, we curated a specialized test set of action-intensive segments selected from the complete annotated classroom videos. This set consists of 100 clips with a duration of 4 minutes and 100 clips with a duration of 8 minutes.

All models were evaluated on the same sampled data to ensure consistency and reliability of the experimental results.

4.2 Teacher Action Recognition

For this task, we specifically introduced two Omni-LLMs, Qwen2.5-Omni and Gemini 2.5 Pro-Omni, to evaluate their performance with full multimodal inputs (video, audio, and text). To isolate and assess the specific contribution of the auditory modality to classroom behavior understanding, we also established a baseline vision-language setting for all ten models. This comparative setup allows us to validate the benefits of supplementary audio information.

We evaluate model performance on both overall accuracy and individual instructional actions, using Accuracy, Precision, Recall, and F1 Score as the primary metrics. As summarized in Table 3, the multimodal Gemini 2.5 Pro-Omni (0.5650 Acc), Qwen2.5-Omni (0.5575 Acc) significantly outperforms its unimodal variant, Gemini 2.5 Pro (0.5325 Acc), Qwen2.5-Omni-Single (0.5150 Acc). This demonstrates that inputs encompassing video, audio, and text enhance a model's ability to capture diverse cues from complex instructional scenes. Furthermore, Gemini 2.5 Pro-Omni achieves the best overall accuracy (0.5650) and a standout precision (0.7363). Closely following are Qwen2.5-Omni and Spark X1. In contrast, LLaMA4-17B displays a high precision (0.6561) but a comparatively low recall (0.4675), suggesting a more conservative prediction strategy.

For individual action categories. The results reveal that actions with distinct and concrete visual features (such as "Write on the blackboard" and "Display teaching aids") tend to be recognized more reliably across models. Qwen2.5-Omni and Spark X1 are particularly strong on such categories, achieving up to 100% accuracy. In contrast, abstract or weakly visual actions such as "Point to the podium" and "Make a bow" remain challenging across the board, often exhibiting recognition accuracy below 10%, as presented in Figure 8. These findings underscore the necessity of cross-modal fusion to resolve visual ambiguity and to improve semantic discrimination in fine-grained instructional behavior understanding.

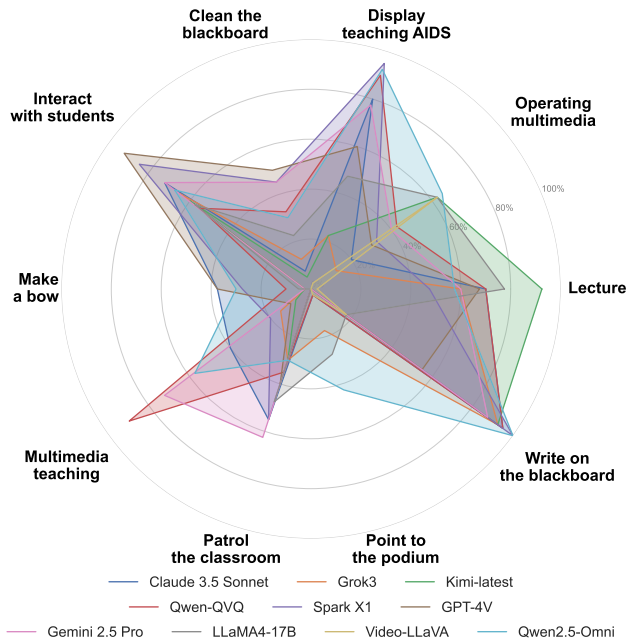

Figure 8: Per-category model recognition accuracy.

Compared to unimodal video inputs, multimodal integration demonstrates superior performance in teacher action recognition tasks. Specifically, the audio modality contributes linguistic content and ambient classroom cues, helping to disambiguate semantically similar actions that are visually confounded. For instance, "Write on the blackboard" and "Clean the blackboard", which appear visually alike but can be distinguished through corresponding audio signals. When writing on the blackboard, teachers often verbalize the content being written, whereas during clean the blackboard, they typically remain silent. The textual modality further enhances the model's understanding of instructional goals and behavioral intent, addressing the limitations of visual data in modeling contextual dependencies.

4.3 Teacher Behavior Temporal Boundary Extraction

To evaluate the temporal localization capabilities of Video-LLMs in continuous video streams, we conducted specific experiments on the Teacher Behavior Temporal Boundary Extraction Subset (TBTB Subset). Although the TBTB Subset provides complete classroom annotations with an average duration exceeding 40 minutes, current Video-LLMs still suffer from significant computational bottlenecks and reasoning deficiencies when processing ultra-long temporal contexts (Long-context), making it difficult to effectively comprehend the complexity of a full lesson. Therefore, we curated a test set by extracting "action-intensive" segments from the TBTB Subset, consisting of 100 clips with a duration of 4 minutes and 100 clips with a duration of 8 minutes. This design aims to maximally test the models' temporal

Table 4: Performance comparison of Teacher Behavior Temporal Boundary Extraction on 4-minute and 8-minute clips. The metrics include tIoU and mAP at different IoU thresholds (0.3 and 0.7).

Model	4min			8min		
	tIoU	mAP@0.3	mAP@0.7	tIoU	mAP@0.3	mAP@0.7
Gemini 2.5 Pro	36.48%	48.89%	6.32%	23.12%	22.43%	0.00%
Qwen2.5-Omni	34.20%	39.67%	4.21%	20.32%	17.64%	0.00%
GPT-4V	29.32%	21.47%	0.00%	16.38%	15.52%	0.00%
Kimi-latest	32.57%	41.09%	3.33%	18.24%	19.73%	0.00%

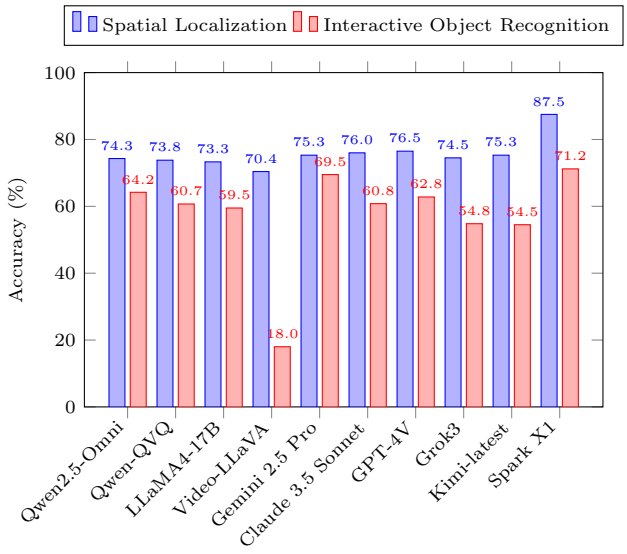

Figure 9: Comparison of Video-LLMs on Spatial Localization and Interactive Object Recognition.

sensitivity within a range accessible to their current capabilities. For evaluation metrics, we employ temporal Intersection over Union (tIoU) to measure the overlap between predicted segments and ground truth annotations. Additionally, we use mAP@0.3 and mAP@0.7 to assess model performance under two distinct strictness levels: "coarse localization" and "fine-grained localization," respectively. The experimental data is presented in Table 4.

The experimental results expose a "Precision Bottleneck" in temporal grounding among current models. While models demonstrate a degree of usability in coarse localization (mAP@0.3) on 4-minute videos (with Gemini 2.5 Pro reaching up to 48.89%), indicating their ability to perceive the approximate intervals of action occurrences; however, performance drops precipitously once precise boundary regression (IoU=0.7) is required. Even the best-performing model achieves an mAP@0.7 of only 6.32% in the shorter 4-minute setting, while some models score 0. This reveals that existing Video-LLMs function more as "semantic event detectors" rather than localizers with high-resolution temporal regression capabilities, failing to meet the demand for precise timestamps in educational analysis.

4.4 Teacher Behavior Spatial Localization

As video duration increases, models exhibit Catastrophic Performance Decay. When the test video duration extends from 4 minutes to 8 minutes, the average coarse localization accuracy (mAP@0.3) across all models drops by approximately 50%, highlighting the difficulty models face in maintaining attention over longer contexts. Most critically, in the 8-minute setting, the mAP@0.7 scores for all tested models fall to zero (0.00%). This "zero-shot failure" phenomenon indicates that as the temporal context expands, the redundancy and accumulation of visual information completely overwhelm the models' fine-grained perception mechanisms, resulting in a total loss of the ability to precisely delineate action boundaries in long continuous streams.

The data reveals a severe Divergence between Semantic Retrieval and Temporal Alignment in Video-LLMs. Although tIoU metrics maintain a range of 16%-37%, suggesting that models can successfully comprehend and retrieve approximate content segments containing the target actions (i.e., "finding the content"), the extremely low mAP@0.7 proves that this semantic understanding does not translate into precise geometric or temporal alignment (i.e., "failing to localize accurately"). This suggests that current architecture designs may over-rely on semantic correlation calculations similar to "image-text matching," while lacking dedicated mechanisms to explicitly model temporal boundary mutations and state transitions.

This dimension measures the model's ability to accurately identify the spatial location and the interaction target of the teacher while performing a specific instructional action.

As shown in Figure 9, all models achieved high performance in the spatial localization task, with accuracy exceeding 70%. This suggests a generalizable capability in recognizing stable spatial configurations commonly found in classrooms. For instance, the podium area is often characterized by frontal blackboards and multimedia screens, while interactions among students are typically associated with dense seating arrangements and more dynamic visual contexts.

In terms of interactive object recognition, model performance varied more significantly. Notably, Spark X1 achieved the highest accuracy in this dimension (71.2%), substantially outperforming other models. This can be attributed to its education-oriented design, which enhances its capacity to attend to pedagogically relevant visual cues and instructional targets. Models such as Qwen2.5-Omni and Gemini 2.5 Pro also demonstrated balanced performance across both spatial and interaction-level reasoning, reflecting strong cross-modal alignment.

Table 5: Text similarity evaluation of different models. Bold values denote the best; Italics values indicate the second-best.

Spark X1	0.2251	0.4740	0.4737	0.5077

The two tasks are inherently interrelated: when teachers are positioned on the podium, their interaction targets are predominantly the blackboard or multimedia devices; When interacting with students, their spatial position typically shifts among students seating area. This spatial-interaction coupling provides mutual semantic cues that can reinforce model prediction accuracy. Together, accurate recognition of spatial positions and interaction targets offers deeper insights into instructional intent and classroom orchestration strategies.

4.5 Teacher Behavior Description

We further evaluate models' ability of video understanding by the teacher behavior description task, using two complementary approaches: traditional textual similarity metrics and semantic scoring via LLM-as-a-judge. In traditional metric-based evaluation, the evaluation results are shown in Table 5 in terms of ROUGE [31], CIDEr [41], BLEU [33], METEOR [4]. Qwen2.5-Omni achieves the highest CIDEr score (0.5097), reflecting its superior ability to reproduce fine-grained instructional details that align with expert references. Gemini 2.5 Pro leads in BLEU (0.2327), METEOR (0.4795), and ROUGE (0.4810), demonstrating a strong balance between surface-level lexical accuracy and semantic fluency. GPT-4V and Claude 3.5 Sonnet exhibit relatively balanced but slightly lower scores across all metrics, while education-oriented model Spark X1 maintains competitive performance, particularly in CIDEr (0.5077), which highlights its alignment with the educational domain.

To further enhance the objectivity and robustness of the evaluation, we introduce the LLM-as-a-Judge [8, 10] mechanism, employing DeepSeek-R1 to compute semantic alignment score for the model-generated teacher behavior descriptions. To ensure the reliability of this automated scoring mechanism, we further introduce GPT-5 to conduct an independent re-check on all teacher behavior description samples and calculate the Pearson correlation coefficient (γ) between its scores and the original scores from DeepSeek-R1. The results show an overall correlation of $\gamma = 0.87$, indicating a high consistency between the two scoring methods.

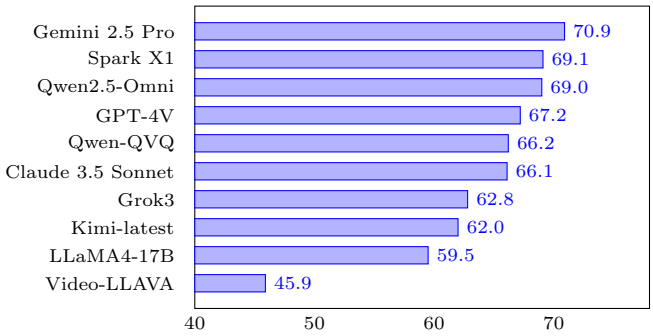

Figure 10: LLM-as-a-judge Evaluation Results for Teacher Behavior Description.

For the samples where $\gamma < 0.8$ (totaling 212 instances), we further invited three experts in the field of education to perform a manual re-evaluation to verify the reasonableness of the scores. This multi-layer evaluation mechanism ensures that both lexical similarity and deep semantic consistency are taken into account, thereby significantly increasing the reliability of our benchmarking results.

Specifically, we design a rigorous 100-point weighted deduction scheme to quantify semantic fidelity, as detailed in Table 6. The scoring framework comprises six dimensions: Core Action Accuracy (30%) serves as the primary metric, imposing the most severe penalties for action misclassification to ensure fundamental validity. Spatiotemporal Localization (15%) and Interactive Object Recognition (15%) jointly evaluate the precision of spatial grounding and target alignment. Content Consistency (20%) strictly penalizes logical contradictions and hallucinations, while Environmental Detail Fidelity (10%) and Linguistic Specification (10%) assess the richness of contextual cues and terminological correctness. This hierarchical weighting strategy ensures that the evaluation prioritizes action-centric semantic precision while maintaining the overall structural coherence of the generated descriptions.

Evaluation scores are presented in Figure 10. Scoring results reveal that Gemini 2.5 Pro(70.9), Spark X1(69.1) and Qwen2.5-Omni(69.0) achieve relatively high semantic alignment, indicating their strong capacity to model key instructional components such as action intent, spatial positioning, and interaction targets. GPT-4V(67.2), Qwen-QVQ(66.2) and Claude 3.5 Sonnet (66.1) followed closely, suggesting a high degree of linguistic coherence, though it exhibited occasional misinterpretations of behavioral details. As an automated semantic evaluation framework, LLM-as-a-judge provides interpretable and discriminative metrics that go beyond surface-level textual overlap, offering deeper insights into whether large models truly comprehend instructional behavior. Scoring examples from DeepSeek-R1 are provided in Figure 11.

5. CONCLUSION

In this work, we addressed the critical need to evaluate Video-LLMs in educational contexts, particularly for teacher behavior understanding. We proposed a multi-stage Human-LLM collaborative annotation pipeline that ensured anno-

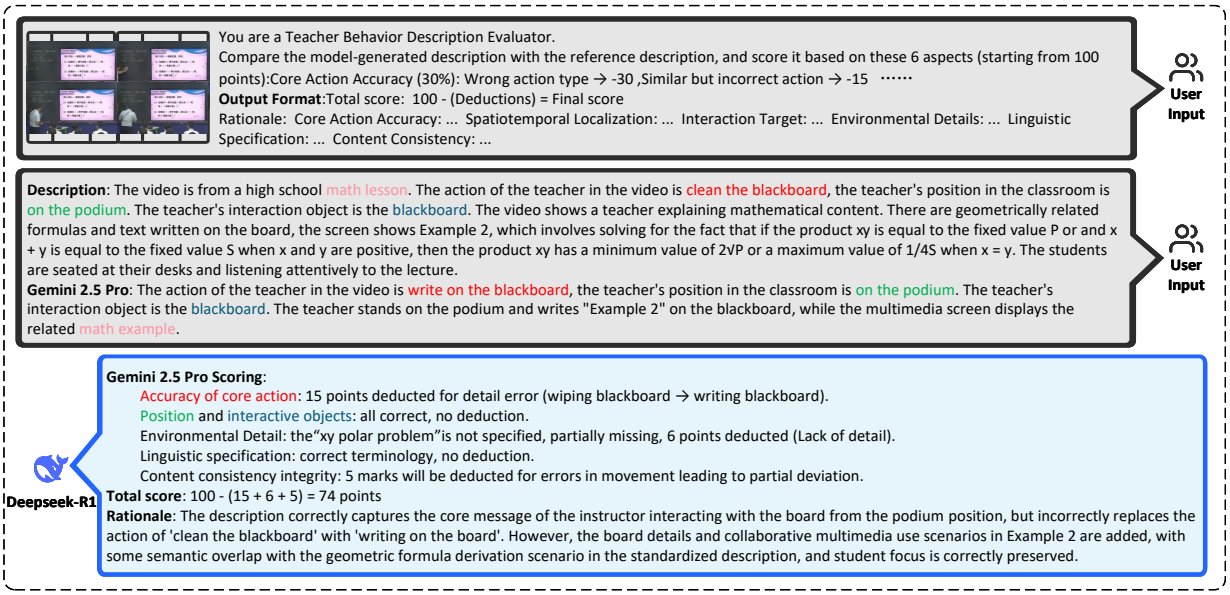

Figure 11: A scoring example of using DeepSeek-R1 to evaluate for teacher behavior description.

Table 6: Semantic evaluation criteria for LLM-as-a-judge ($\alpha + \beta + \gamma + \delta + \epsilon + \zeta = 100\%$).

Evaluation Dimension & Weight	Deduction Rules	Example
Core Action Accuracy ($\boldsymbol{\alpha}\%$)	Directional error: $-\alpha$ Detail-level error: $-\alpha/2$	Describing "clean the blackboard" as "lecture" Describing "lecture" as "multimedia teaching"
Spatiotemporal Localization ($\boldsymbol{\beta}\%$)	Spatial location error: $-\beta$	"on the podium" misjudged as "among students"
Interactive Object Recognition ($\boldsymbol{\gamma}\%$)	Interaction target error: $-\gamma$	"blackboard" misjudged as "multimedia"
Environmental Detail Fidelity ($\boldsymbol{\delta}\%$)	Completely missing details: $-\delta$ Partially missing details: $-\delta/2$	Missing all environmental cues Teacher attire "suit" misjudged as "sportswear"
Linguistic Specification ($\boldsymbol{\epsilon}\%$)	Terminology error: $-\epsilon/2$ to $-\epsilon$ Logical inconsistency: $-2/\epsilon$ to $-\epsilon$	Describing "podium" as "desk" Describe "clean" and "write" at the same time.
Content Consistency Integrity ($\boldsymbol{\zeta}\%$)	Completely off-topic: $-\zeta$	Misjudging a math lesson as historical lesson

tation efficiency and multimodal consistency. Through this pipeline, we introduced **MTBU-Bench**, the first multimodal benchmark tailored for this task, spanning 15 K-12 and higher education disciplines across 300+ classroom scenarios. Through large-scale evaluations of ten mainstream Video-LLMs across action recognition, spatiotemporal localization and behavior description, we uncovered key insights. Firstly, audio and text modalities were critical for disambiguating visually similar behaviors by incorporating verbal cues and contextual intent. Secondly, abstract actions posed significant challenges, highlighting limitations in interpreting weakly visualized behaviors. Thirdly, all models struggled with fine-grained distinctions in interaction targets and temporal boundary extraction in long-form videos. Overall, **MTBU-Bench** provided a rigorous framework for advancing Video-LLMs in education, while our findings highlighted urgent needs for improved temporal modeling, cross-modal alignment, and handling of abstract instructional behaviors. Furthermore, we recognize that our current classroom videos are predominantly sourced from mainland China, which introduces a limitation in cross-cultural generalization. Since instructional norms and spatial layouts vary significantly across cultures, scaling this benchmark to encompass global diverse educational settings remains an important direction for future research. We hope it will inspire further developments in instructional video understanding, MLLMs alignment, and behavior-aware educational applications.

Ethical Statement

The construction of MTBU-Bench was conducted in strict adherence to ethical guidelines for human subjects research and was formally approved by our Institutional Review Board (Approval No. IMU20260402-0017). To safeguard the privacy of participating educators and K-12 students, all Personally Identifiable Information (PII) was systematically removed, and robust facial blurring was applied to recognizable individuals. The dataset is released exclusively for non-commercial, academic research under a strict Data Use Agreement to prevent misuse.

ABSTRACT

This study investigates behavioral signatures in computer-based testing and their relationship to students' test-taking efficiency, contributing a granular behavioral taxonomy that moves beyond rigid archetypes. Using process data from the 2017 NAEP Grade 8 Mathematics assessment (N=1,642), we developed an unsupervised-to-supervised learning framework utilizing Principal Component Analysis and Gaussian Mixture Modeling to identify five core behavioral dimensions (i.e., Navigation Intensity, Problem-Solving Tool Use, UI Interface Interaction, Deliberate Pausing, and Content Interaction Over UI), followed by supervised methods including tree-based model to predict efficiency patterns. Through engineering 43 features, including a Relative Action Intensity Score to standardize interaction density across heterogeneous items, our analysis categorized students into 13 distinct behavioral clusters with efficiency rates ranging from 13% (Impulsive Rushers) to 73% (Strategic Navigators). Our XGBoost model achieved an AUC of 0.729 (Adjusted AUC = 0.458), outperforming all previous approaches from the 2019 NAEP Data Mining Competition. Importantly, we reveal that UI complexity significantly impacts efficiency, with inefficient students disproportionately interacting with interface elements rather than content. Our granular behavioral taxonomy demonstrates that while inefficiency concentrates in specific patterns (particularly impulsive rushing), efficiency emerges through multiple strategic pathways. These results provide evidence-based guidelines for computer-based tests (CBT) design, recommending reduced UI complexity to minimize extraneous cognitive load and accommodate diverse student strategies.

1. INTRODUCTION

Recent technological advancements in the test-taking landscape have shifted traditional paper-based exams toward computer-based tests (CBT). This transition introduces new interaction demands, as students must navigate complex digital interfaces by clicking, dragging, typing, and scrolling while solving assessment items [9]. Such changes highlight the importance of understanding how students engage with CBT interfaces. For instance, for students with limited digital literacy, this can impose additional cognitive load, making it difficult to efficiently complete tests and potentially affecting performance [13]. More critically, this raises concerns about test validity—whether assessments truly measure cognitive abilities in the intended domain or inadvertently assess digital interface proficiency [10, 22, 23]. On the other hand, the transition to CBT enables collection of detailed behavioral data, including clicks, drags, navigational paths, and precise timestamps, which are the data previously unavailable in paper-based tests [14].

This presents opportunities to examine test-taking behaviors comprehensively and investigate how interaction patterns relate to efficiency. Using process data from the 2017 NAEP Grade 8 Mathematics assessment, which contains rich behavioral information from over 1,600 students, this study develops new approaches for understanding and predicting test-taking efficiency in digital environments [20]. Two key research questions guide this study: **(1) What distinct behavioral patterns emerge in students' interaction with computer-based tests?** and **(2) Which behavioral patterns distinguish efficient from inefficient test-taking approaches?**

Our study makes several key contributions: First, we develop a five-dimensional behavioral framework to capture distinct engagement patterns, leading to the identification of 13 behavioral clusters that reveal multiple pathways to efficiency while showing inefficiency concentrates in specific problematic patterns. Second, using these behavioral dimensions as features in supervised machine learning models, we achieve improved predictive performance on test-taking efficiency that substantially outperforms previous approaches including winners of the 2019 NAEP Data Mining Competition [19, 6, 12, 25]. Finally, we provide evidence-based CBT interface design recommendations, particularly regarding UI complexity reduction to minimize extraneous cognitive load. [1]

2. RELATED WORK

The shift toward computer-based testing has enabled researchers to apply educational data mining techniques to understand student behaviors and predict performance outcomes [5]. Process data analysis has emerged as a key approach for examining the sequence and timing of student actions during digital assessments [14].

In particular, the 2019 NAEP Data Mining Competition generated significant research interest in predicting test-taking efficiency, resulting in multiple methodological approaches published in a special issue of the Journal of Educational Data Mining [3]. Bosch (2021) [6] employed AutoML feature engineering using TSFRESH and Featuretools, generating over 4,000 automatically extracted features and achieving an Adjusted AUC of 0.331. However, the limited interpretability of this approach makes it difficult to derive actionable insights for practitioners. Zehner et al. (2021) [25] adopted a top-down psychometric approach, using latent speed and ability models to categorize students into four distinct test-taking types, achieving moderate performance with Adjusted AUC of 0.270. Patel et al. (2021) [19] utilized educational process analysis and fuzzy mining algorithms, focusing on temporal sequences and behavioral prototypes, and achieving Adjusted AUC of 0.326. In particular, they specifically discuss how observed "flipping behaviors" could inform interface design improvements. Levin (2021) [12] won the competition with Adjusted AUC = 0.315 by combining process mining with expert feature engineering, using approximately 330 features reduced to fewer than 30 through iterative selection to build a predictive model.

While these approaches established critical benchmarks, they often relied on binary classifications or rigid process sequences that overlook the multi-dimensional nature of student-interface interactions. Our study advances this literature by proposing a novel five-dimensional behavioral framework spanning across interaction intensity, tool use, and UI engagement, to identify 13 distinct student clusters. By accounting for both interpretability and performance, our model achieves an Adjusted AUC of 0.458, significantly outperforming the original competition winners while offering new insights into how interaction complexities impact testing efficiency.

3. METHODS

3.1 Data Explanation

For this research, we utilized the process data from the 2017 National Assessment of Educational Progress (NAEP) Grade 8 Mathematics assessment. NAEP is the largest and only representative ongoing assessment that measures U.S. students' knowledge and learning experiences in various subjects (e.g., mathematics, reading, science, writing, civics, economics, etc.) across the nation, states, and 27 urban districts, dating back to 1969 [4]. NAEP officially transitioned from paper-based to digitally-based assessment (DBA) for mathematics and reading in 2017 [20]. This transition to DBA has allowed NAEP to collect and archive "process data." Process data includes new types of detailed information beyond merely analyzing students' right or wrong. It captures students' interactions with the assessment platform and tasks, time-stamped records of student-initiated actions (e.g., clicking drawing tools) after viewing an item, logged processes students follow to arrive at answers, the steps or strategies students use for problem-solving, and the resources or tools utilized during assessments. The process data offers valuable opportunities for researchers to explore student test-taking behaviors and determine whether students use their time efficiently during tests [5].

The complete process data from the 2017 NAEP Grade 8 mathematics assessment, as well as Grade 4 mathematics, are available through restricted access by request. However, for this research, we utilized a limited dataset of Grade 8 process data provided by the Educational Testing Service for the NAEP Data Mining 2019 Competition. The competition organizers publicly provided NAEP process data for approximately 2,400 students who took the NAEP test in early 2017, and participants were asked to use this process data to build a behavioral detection model predicting whether students would spend their time efficiently on the test. While the original dataset includes survey questionnaires capturing students' demographic characteristics, their performance, and learning opportunities both in and outside of school, and their broader educational experiences, the competition dataset contains limited information, focusing exclusively on students' test-taking processes and their efficiency (see Appendix A for the full variable list that we were able to access). Nevertheless, acknowledging these constraints, we aimed to maximize the potential of the available data to explore and understand student behaviors in digital assessments.

For the analysis, we utilized four key variables from the complete dataset: (1) StudentID, (2) Observable, (3) EventTime, and (4) Efficiently Completed Block B. The dataset consisted of a total of 1,642 students. From the outset, the competition organizers designated 1,232 students as the training set and 410 students as the test set, and we maintained this original division in our analysis. However, there were no inherent differences in data collection methods or conditions between these two groups; all 1,642 students completed two 30-minute test sections referred to as Block A and Block B, under identical testing conditions. In terms of efficiency, the training set includes 744 efficient, 488 inefficient test-takers and the test set has 248 efficient and 162 inefficient test-takers.

Among the selected variables, the Observable variable was particularly important for our research interest, as it contained information about the specific actions taken by students during the test. Of the initial 42 actions recorded, we included only 38 actions in our analysis. Four actions related solely to procedural interactions necessary for beginning or ending the test (i.e., "Yes," "No," "OK," and "Leave Section") were excluded. The EventTime variable allowed us to examine the duration of individual student actions and the total amount of time students spent on test items.

Regarding the efficiency variable (i.e., Efficiently Completed Block B), the NAEP Mathematics test consisted of two 30-minute blocks (Block A and Block B), each with a fixed set of questions. The objective of the competition was to predict students' efficiency in Block B using their process data from Block A. That is, all predictor features used in our analyses were derived from students' interactions in Block A, and the efficiency outcome was derived from Block B.

The outcome variable was a binary indicator (i.e., True or False) showing whether students spent their time efficiently or inefficiently in Block B. The competition organizers operationalized "efficiency" as: (1) completing all problems in Block B, and (2) allocating a reasonable amount of time to each problem [20]. To determine what constituted a "reasonable amount of time," they conceptually defined it as the minimum possible time needed to solve each problem, and operationalized it by ranking the total time each student spent on each problem in Block B and establishing the 5th percentile as the lower-bound cutoff, applied per problem, such that a student was labeled as "inefficient" if their time on any problem fell below the 5th percentile of all students' time on that same problem, and "efficient" only if they completed all problems and no problem fell below this threshold. Importantly, this operationalization is purely relative and time-based, without consideration of item correctness or validated psychometric standards. The competition organizers themselves acknowledged that defining this threshold is difficult and has limitations [20]. Despite this, the definition of efficiency is built into the competition dataset, and we adopt it as such throughout our study.

3.2 Feature Engineering

Following NAEP's guidance that researchers must develop meaningful variables from process data before deriving insights [16], we conducted feature engineering as described below. As part of our preprocessing and feature engineering approach, we first applied an exploratory Principal Component Analysis (PCA) [11] for feature engineering to the 38 student actions captured by the "Observable" variable. The main purpose of this initial PCA was dimensionality reduction—to uncover underlying dimensions reflecting distinct student test-taking behaviors, which then provided a data-driven foundation for subsequent feature engineering. Building on the categories identified through our initial PCA of student actions, we engineered several quantitative features to capture students' test-taking behavior. The resulting PCA dimensions provided an empirically driven basis for the subsequent feature-engineering phase. Specific variables derived from these PCA-based behavioral dimensions are detailed further in the Results section. We noted that this PCA represents the initial step in the project's analytic workflow, guiding the process of feature engineering. A second, separate PCA as the method for unsupervised learning was conducted later as part of the analytic methods and is described in detail in the subsequent section.

3.2.1 PCA for Feature Engineering

The decision to retain how many principal components was guided by a visual inspection of a scree plot of eigenvalues, where we observed a notable decrease and leveling off of the explained variance after the fourth component, suggesting that additional components beyond the fourth provided diminishing explanatory value. We therefore decided to maintain four dimensions for interpretability, ensuring that meaningful and coherent dimensions representing students' test interactions. Based on the PCA results depicted in Figure 1, we labeled each principal component and categorized the 38 actions for each dimension. We labeled the first dimension as *Problem-Solving Support Actions* which is associated with the actions that directly support students' problem-solving process, such as activating scratchwork modes, drawing, and using calculators. The second dimension is labeled as *Open Response Actions*, and it involves tools directly used for inputting answers, including opening and closing the equation editor. The third dimension was named *Navigation Actions*, which includes the action to navigate between test items, such as clicking Next, Back button, or item-entry actions. The fourth dimension is named *UI Interaction Actions*, and it pertains to interface modifications that are indirectly related to problem-solving, such as zooming, scrolling, and managing timers.

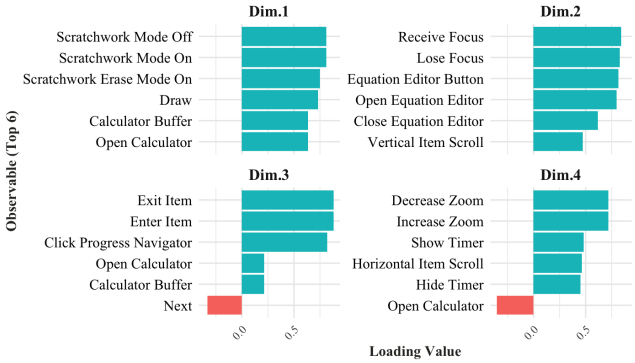

Figure 1: Top Six Contributing Observables in Four Principal Components

Additionally, we found seven actions (e.g., click choice, drop choice, clear answer) that did not align with any specific principal component, as these actions represented essential answering behaviors required across all item types, regardless of students' interaction patterns. These actions were considered together with the four dimensions for feature engineering with the label of *Essential Answer Actions*. Detailed descriptions of 38 actions grouped under each principal component are presented in Table 1. These new categories of the actions were utilized further to create new variables with feature engineering.

3.2.2 Feature Engineering

In addition to the interaction pattern categories identified through our initial PCA of student actions, we engineered several quantitative features to capture different dimensions of student test-taking behavior. As presented in Table 2, we engineered 43 features across five categories of variables: *Interaction Patterns, Time Management, Answer Timing, Hiatus Time, and Navigation Patterns.*

Interaction Patterns. To quantify the density of student interactions across the different action categories as defined above, we developed the Relative Action Intensity Score (RAIS) metric, which standardizes student action counts relative to the average student behavior, and enables meaningful comparisons across students and items by controlling for question-specific interaction items. Specifically, the overall RAIS was calculated by first determining the ratio of a student's action count on each item to the average action count for that item across all students, then averaging these ratios across all items attempted by the student. Values greater than 1.0 indicating above-average interaction intensity and values less than 1.0 indicating below-average interaction intensity.

Table 1: Categorization of 38 Observable Actions into Five Action Categories Based on PCA Results

PC	Name of Category	Actions	# of Actions
Dim 1	Problem-Solving Support Actions	Open Calculator, Close Calculator, Move Calculator, Calculator Buffer, Scratchwork Mode On, Scratchwork Mode Off, Scratchwork Draw Mode On, Scratchwork Erase Mode On, Scratchwork Highlight Mode On, Highlight, Draw, Erase, Clear Scratchwork	13
Dim 2	Open Response Actions	Receive Focus, Lose Focus, Open Equation Editor, Close Equation Editor, Equation Editor Button	5
Dim 3	Navigation Actions	Next, Back, Enter Item, Exit Item, Click Progress Navigator	5
Dim 4	UI Interaction Actions	Change Theme, Hide Timer, Show Timer, Increase Zoom, Decrease Zoom, Text-to-Speech, Vertical Item Scroll, Horizontal Item Scroll	8
Extra	Essential Answer Actions	Click Choice, Math Keypress, Drop Choice, First Text Change, Last Text Change, Clear Answer, Eliminate Choice	7

Table 2: Engineered Features by Category

Categories	Features	# of Features
Interaction Patterns	overall RAIS, problem-solving support RAIS, open response RAIS, navigation RAIS, UI interaction RAIS, essential answer RAIS	6
Time Management	average time per question, time per question variability, essential answer time, essential answer average interval, problem-solving time, problem-solving average interval, open response time, open response average interval, navigation time, navigation average interval, UI interaction time, UI interaction average interval, total time, essential answer proportion, problem-solving proportion, open response proportion, navigation proportion, UI interaction proportion, problem-solving to answer ratio, navigation to answer ratio, open response to answer ratio, UI interaction to answer ratio	22
Answer Timing	time to first answer variability, median time to first answer	2
Hiatus Time	very rapid hiatus percentage (<0.16s), rapid hiatus percentage (0.16-0.5s), normal hiatus percentage (0.5-2.6s), deliberate hiatus percentage (2.6-6.8s), extended hiatus percentage (>6.8s), median hiatus	6
Navigation Patterns	total question switches, forward switches, backward switches, forward movement percentage, unique questions attempted, average revisits per question, maximum revisits per question	7

We then developed dimension-specific RAIS metrics by applying the same computation above to each of the action categories identified from the initial PCA: problem-solving support RAIS measures intensity of optional tool usage (e.g., calculator, scratchwork, drawing tools); open response RAIS measures intensity of interactions with text input and equation tools; navigation RAIS measures forward and backward movements between questions and within the test; UI interaction RAIS measures interface adjustments such as zooming, theme changes, and timer visibility; and essential answer RAIS measures intensity of actions directly required to submit answers. The rationale behind engineering these dimension-specific RAIS metrics is to provide more nuanced behavioral patterns by distinguishing between students who may have the same overall activity levels but distribute their actions differently across interaction types.

Time Management. We engineered 22 temporal features to capture time management patterns. For each student, we calculated average time per question using the difference between the earliest and latest timestamp on each question, as well as time per question variability to measure consistency in time allocation. We then quantified the time spent on each of the five action categories (i.e., problem-solving time, open response time, navigation time, UI interaction time, and essential answer time) by summing the time hiatuses between consecutive actions within each category, with an arbitrarily set upper threshold of 30 seconds to avoid overestimation from extended pauses between different question attempts. For each action category, we also calculated average interval measures (i.e., problem-solving average interval, open response average interval, navigation average interval, UI interaction average interval, and essential answer average interval) to characterize the dispersion of each action type (i.e., how "spaced out" the intervals are per action type). To be more specific, the lower values of these variables suggest

more dense engagement in a category and higher values indicate more dispersed behavior, that students do not perform the certain action regularly.

For comparison across students, we derived proportions of total time spent on each category (problem-solving proportion, open response proportion, navigation proportion, UI interaction proportion, essential answer proportion) and efficiency ratios (problem-solving to answer ratio, navigation to answer ratio, open response to answer ratio, UI interaction to answer ratio) to assess how students distributed their time across different types of interactions.

Answer Timing. We captured students' answering approaches with two features: median time to first answer (i.e., seconds between entering a question and first answer attempt) and time to first answer variability (standard deviation of how quickly a student responds upon seeing a question, measured across all questions). These metrics serve as indicators of comprehension speed, decision-making approaches, and impulsivity in responding. They were calculated separately for different question types (e.g., multiple-choice, fill-in-the-blank, and matching) to account for the varying response mechanisms.

Hiatus Time. We analyzed time gaps between consecutive actions to quantify students' interaction rhythms (i.e., how fast they perform clicks). Based on the overall hiatus distribution across all students, we established five categories and calculated the percentage of actions in each: very rapid hiatus percentage (<0.16s), rapid hiatus percentage (0.16-0.5s), normal hiatus percentage (0.5-2.6s), deliberate hiatus percentage (2.6-6.8s), and extended hiatus percentage (>6.8s). We also calculated median hiatus as an overall indicator of click pace.

Navigation Patterns. We engineered 7 features to capture navigation behaviors: total question switches, forward switches (to later questions), backward switches (to earlier questions), forward movement percentage (proportion of forward-directed moves to capture a predilection toward linear answering strategies), unique questions attempted, average revisits per question, and maximum revisits per question (where a revisit was defined as returning to a previously seen question after having navigated away from it). These metrics collectively capture students' sequencing strategies and tendencies toward linear progression versus non-linear back-and-forth exploration of the test content.

Upon engineering all features, we standardized most of them using z-score normalization to ensure comparability across different scales. However, we preserved the original values of RAIS features (already normalized relative to average student behavior), any proportion/percentage features (bounded between 0-1), and ratio features (inherently comparable across students) to maintain their interpretability. To prevent data leakage, test data features were standardized using means and standard deviations derived exclusively from the training dataset.

3.3 Analytic Method

The analytic approach of this study was conducted in two distinct phases: unsupervised learning and supervised learning. This methodological structure allowed for an initial exploration of behavioral patterns without predefined labels, subsequently informing predictive modeling of efficiency.

3.3.1 Unsupervised Learning

We implemented unsupervised learning techniques to systematically identify and describe students' test-taking behaviors. Following the creation of the engineered features, we conducted a second PCA to further distill these features into coherent behavioral patterns that reflect underlying student test-taking strategies. Based on the results of this PCA, we applied Gaussian Mixture Modeling (GMM; [21]) to cluster students into groups characterized by similar test-taking behaviors as captured by the PCA. We leverage GMM for this task as it offers a probabilistic approach to clustering. Specifically, unlike deterministic methods such as k-means that assign each student to a fixed cluster membership, GMM acknowledges students' varying combination and extent of behavioral patterns as existing along a continuum with fuzzy boundaries, offering a probabilistic interpretation [21].

3.3.2 Supervised Learning

The supervised learning phase of this research consisted of systematically applying predictive modeling techniques based on variables derived from the previous unsupervised learning stage. Using the training data (n = 1232), we trained predictive models based on the PCA-derived behavioral dimensions, feature-engineered variables, and student clusters from our unsupervised analyses. Specifically, we employed tree-based methods—Decision Tree, Random Forest [7], and XGboost—to predict students' test-taking efficiency using all engineered features.

For Decision Tree modeling, we implemented 10-fold cross-validation to identify the optimal complexity parameter, exploring values from 0.0001 to 0.1. This tuning process balanced model complexity and predictive power while preventing overfitting. The final tree was visualized to examine decision pathways that distinguished efficient from inefficient test-takers. We then implemented the Random Forest model using ranger for computational efficiency, applying a similar 10-fold cross-validation but with hyperparameter optimization including mtry values of 2, 4, 6, 8, 10, and 12 (variables considered at each split), min.node.size values of 1, 2, and 3 (minimum observations in terminal nodes), and gini splitrule criterion. This approach generates an ensemble of decorrelated trees to reduce variance while maintaining predictive power. Lastly, for XGBoost, we employed a multiparameter tuning strategy with 5-fold cross-validation, optimizing boosting rounds (50, 100), max depth (3, 6), learning rate (0.1, 0.3), and subsampling rates for both observations and features (0.7-1.0). For all three models, we evaluated and compared accuracy, sensitivity, specificity, and Area Under the Curve (AUC) on the held-out test data (n = 410), then extracted the top 15 most important features identified by the model with the highest AUC. We also report the Adjusted AUC (which is equivalent to the Gini coefficient), calculated as $2 \times (\text{AUC} - 0.5)$, to directly compare with prior competition results [20]. Note that unlike conventional AUC, which has a chance level of 0.5, the Adjusted AUC is rescaled such that a value of 0 indicates chance-level performance and 1 indicates perfect discrimination. The

supervised-learning analytic framework provided not only predictive power but also interpretative clarity regarding how distinct behavioral patterns contributed to efficient or inefficient test-taking behaviors.

4. RESULTS

4.1 Unsupervised Learning

4.1.1 PCA for Behavioral Dimensions

As the first unsupervised learning, we conducted the PCA with 43 feature-engineered variables. The decision to retain how many principal components was again guided by a visual inspection of a scree plot of eigenvalues, where we observed a notable decrease and leveling off of explained variance after the fifth component. Therefore, we decided to maintain five dimensions which collectively explained 62% of the variance in user interactions. Figure 2 displays the top ten contributing variables for each retained principal component. Based on the factor loadings we labeled each dimension (see Table 3).

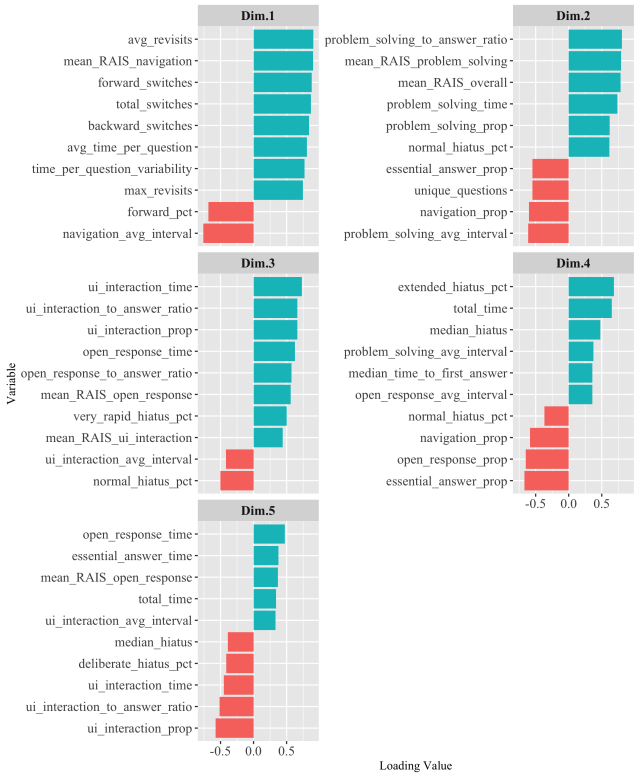

Figure 2: Top Ten Contributing Variables in Five Principal Components

Dimension 1: Navigation Intensity. This dimension is primarily characterized by variables such as average revisits, forward switches, total switches, and backward switches, all of which are strongly and positively associated with item-switching behavior. In contrast, navigation average interval and forward percentage negatively correlated with this dimension Given this, we interpret Dimension 1 as a measure of navigation intensity. A higher score suggests that students frequently revisit and switch between different sections within short time gaps, engaging in more active and fragmented navigation. Conversely, a lower score indicates students navigate less frequently and with longer intervals between transitions, suggesting a more deliberate, linear, or less exploratory approach to problem-solving.

Dimension 2: Problem-Solving Tool Use. Dimension 2 is marked by high positive loadings on variables related to problem-solving behaviors, such as problem solving to answer ratio, problem solving time, and mean RAIS problem solving. In contrast, it exhibits negative loadings for variables associated with other types of engagement, including essential answer prop and navigation prop. This suggests that students with higher scores in this dimension primarily engage in problem-solving tool use, focusing their efforts on problem-solving rather than other behaviors such as submitting essential answers or navigating between sections.

Dimension 3: UI Interface Interaction. This dimension is predominantly associated with UI interaction-related variables, such as UI interaction time, UI interaction to answer ratio, and UI interaction prop, all of which exhibit strong positive loadings. Therefore, we interpret Dimension 3 as measuring the extent to which students engage with the user interface. A higher score in this dimension indicates students who frequently interact with the UI elements. It aligns with the negative value of the UI interaction average interval. The higher factor loading of this variable (i.e., the negative value of this dimension) indicates students less frequently interact with UI and with longer intervals between transitions, which suggests a more deliberate and less exploratory approach to UI interaction.

Dimension 4: Deliberate Pausing. Dimension 4 is characterized by positive loadings on variables related to time spent before taking action, including total time, extended hiatus percentage, and median time to first answer. Meanwhile, it exhibits negative loadings on variables reflecting active engagement, such as essential answer proportion and open response proportion. This pattern suggests that students with higher scores in this dimension engage in deliberate pausing and contemplation, as indicated by longer total time spent, more frequent and extended hiatuses, and slower initial responses. Conversely, lower scores in this dimension indicate a higher relative proportion of active engagement behaviors, such as providing open-ended responses, submitting essential answers, and frequently navigating through the interface. These students tend to engage in actions more frequently rather than deliberately pausing for extended periods.

Dimension 5: Content Interaction Over UI. This dimension is positively associated with variables related to content engagement, such as open response time and essential answer time, while it is negatively associated with UI interaction variables. Based on this pattern, we interpret Dimension 5 as a measure of content-focused interaction versus UI-focused interaction. Students with higher scores in this dimension spend more time engaging with content, such as responding to open-ended questions and providing essential answers. In contrast, students with lower scores demonstrate a greater focus on UI interactions rather than content engagement.

Table 3: The Characteristics of Each Dimension and The Label of Them

Principal Component	Positive Scores (+)	Negative Scores (-)	Name of Dimension
1: Navigation Intensity vs. Efficiency	Frequent question-switching, multiple revisits, non-linear approach	Linear progression, fewer revisits, efficient navigation	Navigation Intensity
2: Problem-Solving Tool Utilization vs. Direct Answering	Heavy use of calculators and tools, high problem-solving time	Focus on direct answering with minimal tool use	Problem-Solving Tool Use
3: Interface Interaction vs. Content Focus	Significant time spent adjusting UI and test environment	Minimal interface adjustment, greater focus on content	UI Interface Interaction
4: Deliberate Pausing vs. Continuous Engagement	Extended pauses, deliberate reflection before answers	Continuous engagement, fewer pauses, faster responses	Deliberate Pausing
5: Content Interaction vs. Interface Adjustment	More time on responses and engaging with question content	More time adjusting interface relative to answering	Content Interaction over UI

4.1.2 Gaussian Mixture Modeling

Following the dimension reduction through the second PCA, we employed GMM to identify distinct clusters of students based on their test-taking behaviors as captured by the principal components. To determine the optimal number of clusters, we evaluated models with 2 to 16 clusters using the Bayesian Information Criterion (BIC). As shown in Figure 3, the VVE model (i.e., variable volume, variable shape, equal orientation) achieved the highest BIC values, peaking at 13 clusters before beginning to plateau[2]. In the context of clustering students by behaviors, the VVE model thus suggests that students' test-taking strategies may have varying prevalence (variable volume) and the degrees of dispersion across dimensions (variable shape); nonetheless, while they demonstrate different behavioral tendencies, the underlying relationships between these behavioral dimensions remain consistent across groups (equal orientation). Based on this analysis and considerations of interpretability, we selected the 13-cluster VVE as the optimal GMM model for capturing the diversity of behavioral patterns in our data.

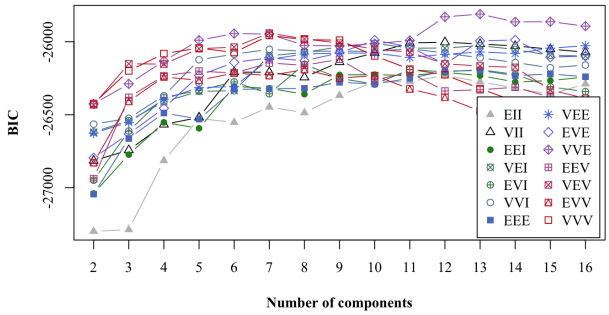

Figure 3: Gaussian Mixture Model Selection

The heatmap in Figure 4 visualizes the 13 identified student clusters, each with distinct behavioral patterns across the five principal components. Note that the dimension values are normalized across the student population, with a value of 0 representing the average behavior, while values further from 0 (either positive or negative) indicate more extreme deviations from the typical behavior patterns. The magnitude of a value indicates how strongly the particular behavioral pattern characterizes that cluster.

Table 4 presents the number of students per cluster and the percentage of efficient students within the cluster, along with more detailed interpretations of their key characteristics and notable behavioral dimension scores. Based on these hallmarks, we coined the names for each cluster. Note that the taxonomic naming convention of each cluster profile only captures the most distinct characteristics of the cluster for interpretability purposes, and should not be understood as defining the cluster or categorizing the students themselves. Furthermore, while cluster labels are grounded in observed behavioral patterns, they remain interpretive in nature.

The GMM clustering results on identified principal components reflect several implications. Firstly, there are multiple pathways to efficiency, but inefficiency concentrates in a few specific behavioral patterns. Specifically, while the percentage of efficient students vary somewhat gradually from Cluster 13 (73%) to Cluster 2 (41%), there is a dramatic drop to Cluster 3 (13%), where the overwhelming majority (87%) of students exhibit inefficient test-taking behavior. This *Impulsive Rushers* group (Cluster 3) demonstrates extremely low deliberative pausing (Dim 4: -4.87), minimal problem-solving tool utilization (Dim.2: -2.20), and disproportionate UI interface interaction over actual content engagement (Dim.5: -1.77). This combination of behaviors portrays the cluster as students who fiddle around with UI

[2]Note that typically when using BIC for model selection, the lower BIC values indicate better models; however in the Mclust implementation in R, the reported BIC is calculated with the negative sign from the standard BIC formula is removed, therefore higher values indicate better models.

Table 4: Description of Cluster Profiles (Ordered by % of Efficient Students per Cluster)

Cluster #	n	% of Efficient Students	Student Cluster Profile
13	98	73%	**Strategic Navigators:** Exhibit extremely high navigation intensity (Dim.1: 4.96) with limited tool utilization (Dim.2: -2.56). They take deliberate pauses when needed (Dim.4: 0.55). Their strategic navigation between questions appears highly effective.
11	120	68%	**Deliberate Pausers:** Characterized by taking thoughtful pauses (Dim.4: 1.63) while minimizing navigation switching (Dim.1: -1.22), tool usage (Dim.2: -1.66), and UI interaction (Dim.3: -0.89), reflecting a focused approach.
5	151	66%	**Interaction Minimalists:** Show consistently low scores across most dimensions, particularly avoiding excessive navigation (Dim.1: -2.65) and UI interactions (Dim.3: -1.22). They take a streamlined and economical approach with continuous progression and minimal usage of supplementary tools.
1	134	64%	**Balanced Reflectors:** Demonstrate positive but moderate scores across most dimensions with notable deliberate pausing (Dim.4: 1.24) and moderate navigation patterns (Dim.1: +0.91).
8	26	62%	**Reflective Pausers:** Show notably reduced navigation activity (Dim.1: -3.55) but very high scores on deliberate pausing (Dim.4: 4.19). They spend more time considering their responses but generally do not switch back and forth between questions.
12	106	61%	**Navigation-Tool Integrators:** Exhibit high navigation intensity (Dim.1: 3.80) with above-average tool usage (Dim.2: 1.99) while minimizing interface distractions (Dim.3: -1.44). They strategically leverage both navigation and problem-solving tools.
6	201	60%	**Interface-Oriented Moderates:** Exhibit moderate UI interaction engagement (Dim.3: 1.35) while showing below-average navigation and problem-solving tool usage. Their somewhat balanced approach avoids extremes in any dimension while moderately interacting with the UI.
7	109	59%	**Tool Maximizers:** Distinguished by very high problem-solving tool usage (Dim.2: +4.79) with moderate interface interaction (Dim.3: +0.63), reflecting that they mostly rely heavily on tools such as the scratchpad and the calculator.
4	41	59%	**Interface-Active Switchers:** Demonstrates extremely high navigation intensity (Dim.1: +4.24) and interface interaction (Dim.3: +3.42), signifying frequent transitions between test items with extensive usage of UI interface elements.
9	53	55%	**Tool-Interface Dwellers:** Show extremely high interface interaction (Dim.3: 4.26) combined with high tool utilization (Dim.2: 2.34) but very low content interaction (Dim.5: -3.46). They focus heavily on UI elements and problem-solving tools rather than direct content engagement.
10	118	53%	**Interface Avoiders:** Characterized by limited usage of available assessment infrastructure with minimal UI interface engagement (Dim.3: -2.16).
2	44	41%	**Conservative Users:** Show consistently negative scores across all dimensions, particularly low in navigation (Dim.1: -2.43) and tool utilization (Dim.2: -3.07), suggesting minimal interactions.
3	31	13%	**Impulsive Rushers:** Exhibit extremely low deliberate pausing (Dim.4: -4.87) and tool utilization (Dim.2: -2.20). They also show substantial imbalance toward interface adjustment over content interaction (Dim.5: -1.77), spending more time manipulating UI elements than engaging with questions. Overall they show a combination of hurried progression with minimal pausing and poor content focus.

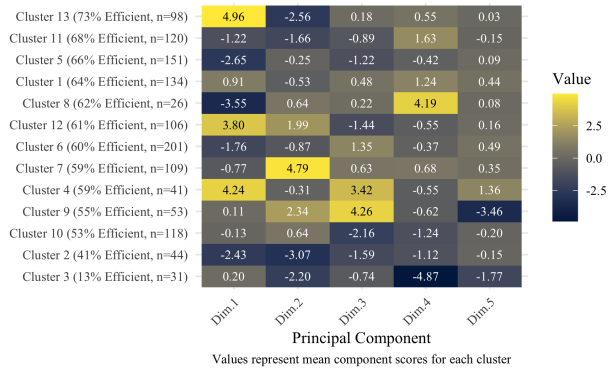

Figure 4: Cluster Profile Across Principal Components (ordered by % of efficient students per cluster)

interface changes without engaging in the actual assessment content, rushing through questions while barely leveraging support tools like the scratchpad and calculator.

Secondly, deliberative pausing (Dim.4) emerges as an important factor for achieving efficiency. Including *Strategic Navigator* (73% efficient students), *Deliberate Pausers* (68% efficient students), *Balanced Reflectors* (64% efficient students), and *Reflective Pausers* (62% efficient students)—Clusters exhibiting above-average deliberate pausing behaviors—all achieved efficiency rates exceeding 62%. Conversely, as aforementioned, *Impulsive Rushers* (which has the lowest percentage of efficient students) showed the most extreme negative value on this dimension (Dim.4: -4.87). This result aligns with Wise's [24] findings that "rapid-guessing behavior"—which test-takers spend very short time responding to multiple-choice items—indicates disengaged test-taking regardless of whether the assessment is low- or high-stake.

Thirdly, when interpreting clusters, the behavioral dimensions would be better to be considered and compared holistically rather than as isolated, deterministic factors. For example, *Strategic Navigators* (Cluster 13) achieved the highest efficiency (73% efficient students) through a distinctive combination of extremely high navigation intensity (Dim.1: 4.96) and minimal problem-solving tool utilization (Dim.2: -2.56), reflecting that they strategically move between questions and do not rely on computational aids such as the calculator or scratchwork features. This suggests that their efficiency may stem not only from their behavioral strategy but potentially also from stronger content knowledge or computational proficiency [1], though such interpretation requires further validation through external achievement data or cognitive measures beyond what current process data alone can provide.

4.2 Supervised Learning

4.2.1 Tree-Based Models

The three tree-based algorithms, all trained on the full set of 43 engineered features, yielded varying performance. As shown in Table 5, XGBoost outperforms both Decision Tree and Random Forest models across accuracy (0.688), sensitivity (0.859), and AUC (0.729). Random Forest achieved marginally better performance than Decision Tree in terms of accuracy (0.659 vs. 0.656) and AUC (0.698 vs. 0.682), though Decision Tree exhibited slightly higher sensitivity (0.815) than Random Forest (0.806). We note that all three of our tree-based models have outperformed the best AUC scores of the winners of the NAEP Data Mining Competition 2019 [19]. Specifically, our best model XGBoost with Adjusted AUC of 0.458 represents a 45.4% improvement over the original competition winner Levin [12] (2021) with Adjusted AUC of 0.315. While these gains are meaningful, an Adjusted AUC of 0.458 reflects only moderate predictive strength, indicating that behavioral process data alone provides useful but limited signal for predicting test-taking efficiency.

Table 5: Model Performance Comparison of Tree-Based Methods

Metric	Decision Tree	Random Forest	XGBoost
Accuracy	0.656	0.659	0.688
Sensitivity	0.815	0.806	0.859
Specificity	0.414	0.432	0.426
AUC	0.682	0.698	0.729
Adjusted AUC	0.364	0.396	0.458

A notable pattern across all three models was the substantial gap between sensitivity and specificity metrics. While sensitivity values ranged from 0.806 to 0.859, specificity values were considerably lower, ranging from 0.414 to 0.432. This indicates that the models were much more successful at identifying efficient test-takers than detecting inefficient ones, which can be partly attributed to the class imbalance in the dataset.

As shown in Figure 5, the feature importance analysis from the best-performing XGBoost model (with highest AUC) demonstrates that median time to first answer is the most influential feature, highlighting that the deliberative thinking process between viewing a question and beginning to answer serves as a critical efficiency marker. Other highly ranked features included navigation time (time spent moving between questions), and total time (overall test duration). Overall, we can see that among the top 15 features, most are related to navigation, hiatus, and essential answer actions, indicating how students move through the test, their rhythm and pacing of interactions, and their engagement with the actual test content contribute most significantly to predicting their efficiency. These findings align with our unsupervised learning results, particularly the identification of dimensions like "Navigation Intensity" and "Deliberate Pausing" in our PCA.

Our decision tree modeling (see Appendix B), which visualizes specific decision paths and identifies key threshold values that distinguish efficient from inefficient test-taking behaviors, complements the results from our XGBoost feature important analysis. Unlike feature importance rankings, which only indicate variables' predictive power, this decision tree reveals specific conditional relationships between variables and their directional impact on efficiency. At the root node, total time serves as the primary splitting criterion, with both lower and higher values potentially leading

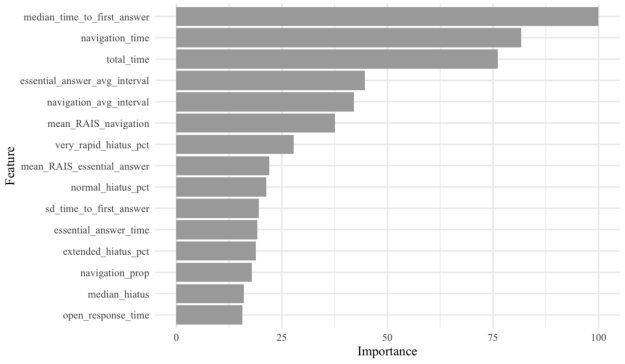

Figure 5: Top 15 Features by Importance in XGBoost

to efficiency depending on subsequent behaviors. This immediately challenges the notion that faster test completion consistently yields greater efficiency.

5. DISCUSSION

In this study, we aimed to understand students' distinctive interaction behaviors with the testing interface and their impact on test-taking efficiency. To achieve this, we applied unsupervised learning (i.e., PCA and GMM) and supervised learning (i.e., tree-based models) to NAEP 8th-grade Mathematics process data. Our findings highlight key behavioral dimensions that affect test taking efficiency and provide insights into optimizing CBT.

PCA revealed five major behavioral dimensions: Navigation Intensity, Problem-Solving Tool Use, UI Interaction, Deliberate Pausing, and Content Interaction Over UI. These dimensions captured distinct engagement patterns among students. GMM clustering further demonstrated the diversity of test-taking strategies, identifying 13 student clusters with varying efficiency levels. Notably, Navigation Intensity and Deliberate Pausing emerged as strong indicators of efficiency, aligning with previous research on test-taking strategies [19]. Our analysis found that disengagement and impulsive rushing—characterized by minimal pausing, high UI interaction, and low content engagement—significantly reduce efficiency. Conversely, high-efficiency clusters demonstrated a balance of navigation, deliberate pausing, and content-focused engagement rather than excessive reliance on UI interactions or problem-solving tools. The tree-based models further corroborated these findings, highlighting *median time to first answer* as the strongest predictor of efficiency. This affirms the significance of deliberative engagement; as such, supporting behaviors like structured pauses and reduced rapid navigation could improve test-taking performance.

While our supervised tree-based models suggest that features related to UI interaction and tool usage do not have important predictive powers (i.e., we may not able to label the students' efficiency based on the UI interaction), our unsupervised learning discloses that these features distinguish clusters with higher percentages of efficient students from those without. The 60 percentage point efficiency gap between our highest and lowest performing clusters (Strategic Navigators at 73% vs. Impulsive Rushers at 13%) suggests that interface design choices can substantially impact students' test-taking behavior and which can eventually hinder the interpretation of the test score. From this, we can interpret that reducing the extraneous cognitive load from UI complexity is still a crucial consideration for optimizing interface designs [8, 18, 17].

These findings have broader implications beyond traditional NAEP mathematics assessments. To enhance engagement and efficiency while taking the test, interfaces should minimize unnecessary UI elements that may distract students from content engagement [18], preventing "mouse skills" from masking their actual "math skills." Additionally, adaptive testing interfaces that recognize and respond to inefficient navigation patterns could offer real-time support to students struggling with disengagement or impulsive rushing. Assessment designers should also consider how structured pauses and deliberate engagement can be facilitated to help enhance students' test-taking efficiency [2]. While our analysis is limited to the context of computer-based testing on NAEP, future validation across different computer-based tests across different subject areas would strengthen the practical applicability of our taxonomy.

5.1 Limitations and Future Work

This study has several limitations that should be considered when interpreting the findings. First, one major limitation is the lack of demographic data. As noted in the data description, the dataset does not include information on socio-economic status (SES), gender, or prior digital exposure, which may affect students' interaction behaviors and efficiency in CBT. However, there is an opportunity to obtain these variables by contacting the NAEP through a formal request. Future research could explore these factors further if access to such data is granted. For instance, the role of SES in digital literacy and assessment performance warrants further investigation. The lack of digital literacy skills can exacerbate existing educational inequalities, disproportionately affecting students from lower socio-economic backgrounds who may have limited access to technology and digital learning resources.

Second, as another crucial limitation, the dataset does not include item-level accuracy information (i.e., information about whether students answered correctly or incorrectly on each item), and the efficiency metric itself is inherited from the competition design [20]. This raises concerns about construct validity [15]. For instance, high-performing students who solve problems quickly and correctly may be systematically labeled as inefficient, while students who spend time on problems without productive engagement may be labeled as efficient. Future research should integrate additional data sources, such as item-level accuracy and cognitive measures, to both develop efficiency measures that jointly consider time and correctness, and to further validate the behavioral cluster interpretations identified in this study.

Third, in terms of analytic method, this study solely focused on individual student behaviors, without considering item types, which may significantly impact interaction patterns. For example, actions such as "Lose Focus" or "Receive Focus" occur exclusively in "Fill in the Blank" item format, yet our analysis did not account for such item-specific behaviors.

Future studies with access to a larger and more diverse set of item types should investigate how students' behaviors vary by question format.

We hope, addressing these limitations will help advance research on computer-based testing and student interaction behaviors. Expanding datasets to include demographics, diverse item types, and performance-based efficiency metrics will allow for a more comprehensive analysis. Additionally, refining predictive models by incorporating more behavioral and cognitive factors can improve our understanding of effective computer-based test-taking strategies and inform adaptive assessment designs that better support student learning.

APPENDIX
A. DATASET VARIABLES

Table A: Variables in Publicly Accessible Raw Datasets

Variable Name	Description	Values/Categories	Sample Size
Student ID	Unique identifier for each student	Numeric ID	N = 1232
Block	Test block identifier	Block A, Block B	
Accession Number	A unique identification of a problem/item	Item IDs (e.g., "VH356862")	N = 24
Item Type	The type of the item	MCSS (Multiple-choice single-selection question), GridMS (Grid-style multiple-selection question), MatchMS (Match multiple-selection question), ZonesMS (Multiple selection of pre-defined zones), FillInBlank (Single fill in the blank question), MultipleFillInBlank (Multiple fill in the blank question), CompositeCR (Composite constructed response question (e.g., open-ended)), BQMCSS (Background/Survey MCSS question)	N = 8
Observable	Action taken by student	Enter Item, Next, Exit Item, Click Choice, Open Calculator, Move Calculator, Calculator Buffer, DropChoice, Eliminate Choice, Vertical Item Scroll, Receive Focus, Math Keypress, Lose Focus, Close Calculator, Click Progress Navigator, First Text Change, Yes, Leave Section, Scratchwork Mode On, Draw, Scratchwork Mode Off, Scratchwork Erase Mode On, Erase, Scratchwork Draw Mode On, Scratchwork Highlight Mode On, Highlight, Clear Answer, Change Theme, TextToSpeech, Open Equation Editor, Equation Editor Button, Clear Scratchwork, OK, Close Equation Editor, Back, Increase Zoom, Decrease Zoom, Hide Timer, Show Timer, Last Text Change, No, Horizontal Item Scroll	N = 42
Extended Info	Additional metadata about the action	Various metadata strings. Metadata of the student action in a JSON format e.g. how much did the student scroll, what key she pressed on the calculator, what digit she typed as a response, etc.	Average 356 actions per student in the training set and 117 actions in the test set
Event Time	The timestamp of when the action was taken	Datetime format (e.g., "2017-02-10 14:44:54.167")	
Efficiency	Outcome variable indicating efficient completion of Block B*	TRUE/FALSE**	

* All predictor variables of both training and test sets of the data are from Block A interactions, while the outcome variable (i.e., EfficientlyCompletedBlockB) is derived from Block B performance.
** TRUE means "efficient" and FALSE means "inefficient". The efficiency is defined based on the usage of the time as 1) being able to complete all problems in Block B, and 2) being able to allocate a reasonable amount of time to solve each problem. Detailed information can be found here.

ABSTRACT

Modern electrical grid systems demand engineers capable of adaptive reasoning, systematic justification, and principled decision-making under uncertainty. However, while many graduates excel technically, they often struggle with these expert-level competencies, revealing gaps in our understanding of expertise development. To address this, we need to identify the granular cognitive and epistemic shifts that occur along the expertise continuum. Drawing on Epistemic Frame Theory, this study examines how epistemic frames shape the developmental trajectory of expertise across second-year, third-year, and final-year undergraduates, compared against field professionals (experts). In the study, participants completed an open-ended electrical grid design task in a computer-based environment. We applied Min-Max normalization to verbal protocols to neutralize verbosity bias and reveal latent structural shifts. Our findings highlight a two fundamental developmental trajectories. An ascending trajectory captures the adoption of a professional lens, wherein students transition from academic idealism to professional pragmatism and from reactive debugging to proactive modeling. Conversely, a descending trajectory reflects the shedding of novice habits, indicating a gradual disengagement from surface-level and trial-and-error strategies. Notably, experts' strategic silence emerged as a marker of proficiency. We observed that experts' silence is a signal of proficiency. The high-frequency behaviors in novices, such as visual monitoring and explicit naming of components, fade away as knowledge becomes tacit. These findings suggest that expertise is defined as much by what is shed (novice habits) as what is acquired (professional lens). These insights suggest that engineering curricula should incorporate earlier authentic practice to bridge the theoretical trap fostering the transition from explicit theoretical rules to implicit professional norms.

Epistemic Frame Theory, Trajectory of Expertise, Continuum of Expertise, Min-Max Normalization, Engineering Education

1. INTRODUCTION

A purpose of formal education is to enable students to build domain-specific knowledge, ways of thinking, and professional practices that are essential for successful learning and to develop expertise in it [24, 28, 19]. The most important part is that expertise is not a general body of knowledge; it is grounded in numerous context-specific experiences. Expert knowledge is typically deeply tied to particular domains and develops through sustained participation in authentic practice [18]. The expertise acquired in a particular domain shapes professional expertise in that domain. [15]. Expertise is developed through progressive stages, with each stage characterized by qualitative transformations in how individuals perceive situations and make decisions [13, 20, 4, 27] [18].

The modeling of expertise through progressive stages is extensively discussed in foundational research, most notably in *the Dreyfus model of skill acquisition* [13], *the Benner mode* [4], *the Two expertise model* proposed by Hatano and Inagaki [27, 7]. *The skill acquisition model* proposed by Dreyfus and Dreyfus [13] is stage-based model, it conceptualize expertise as a progression through qualitatively distinct stages of novice, advanced beginner, competent, proficient and expert. This model emphasize changes in rule-following, intuition, and situational perception as individuals accumulate skills. Such models have been influential across professional domains. Benner [3] adapted Dreyfus' five-stage model of

https://doi.org/10.5281/zenodo.21039873

skill acquisition to nursing domain. Hatano and Inagaki [27], and later Carbonell in 2019 [7], differentiate between *routine experts* and *adaptive experts*. The routine experts are ones who perform efficiently in familiar situations and Adaptive Experts are who can transfer knowledge and creatively solve novel problems. Adaptive expertise builds on routine expertise, is shaped by task variety, and reflects a dynamic rather than static view of knowledge. Alongside the stage-based models of expertise, there are *cognitive theories* for problem solving strategies [9, 2, 34], *Mental models and situation awareness* that explain experts' superior anticipation of system behavior [22, 16] and *knowledge-based model* [15, 16, 17]. These existing models are predominantly cognitive, focusing on technical skills, social participation, and situational experiences.

Recent studies apply distinct theoretical lenses to understand the trajectory of professional development. Lyon [36] utilizes the Dreyfus model to structure the linear stages of teaching development in dental education. Dehn et al.[11] analyze the guided Self-Determination model, revealing the complex, multidimensional factors that drive skill acquisition beyond simple proficiency in nursing education. Furthermore, Kua et al.[32] examine Hatano's concept of adaptive expertise to highlight the necessity of cognitive flexibility in educational settings; they are specifically examining the epistemology. Although these models of expertise are useful for characterizing differences between novices and experts, they offer limited guidance for designing targeted interventions as they lack empirical evidence about when and how key transformations in expertise actually occur. Moreover, beyond cognitive dimensions such as skills and knowledge, existing models provide little clarity about which additional dimensions (e.g., identity, values, or professional judgment) contribute to more fine-grained developmental progressions.

This theoretical limitation is further compounded by a measurement challenge. As individuals develop expertise, what they choose to verbalize changes systematically. Empirical expert–novice studies show that experts often articulate fewer foundational concepts than novices because much of their domain knowledge becomes automated and tacit [1, 9, 34]. Consequently, traditional frequency-based analysis methods risk misinterpreting reduced verbalization as disengagement or conceptual weakness rather than recognizing it as a potential marker of proficiency. Addressing this issue requires both a multidimensional theoretical framework and analytical methods capable of this verbosity confound.

In this paper, we propose a multi-model expertise development, operationalized through Epistemic Frame Theory (EFT) [44, 42]. EFT conceptualizes a network of interconnected components, where individuals' engagement and practice within a community shape the development and organization of epistemic frames (Shaffer, 2006a). Epistemic frame theory suggests that every profession has unique collections of *Skills* (practical actions professionals perform), *Knowledge* (conceptual understanding professionals possess), *Values* (what are the believes of professionals and what they consider important), *Identity* (how professionals see themselves and their role), and *Epistemology* (how professionals justify decisions and determine valid reasoning) that construct an epistemic frame.

We move beyond simple usage counts to uncover the changing meaning of these epistemic frames. By applying Min-Max normalization to verbal protocols across four cohorts (second year, third year, final year, and a field professional), we neutralize verbosity bias to reveal two complementary developmental trajectories:

- Ascending Trajectories: The adoption of the professional lens
- Descending Trajectories: The shedding of novice habits

This developmental map provides a benchmark for designing stage-appropriate educational interventions. It identifies not only which expert-like behaviors emerge and should be reinforced through scaffolding, but also which persistent novice habits require explicit pedagogical attention to accelerate their decline. By revealing both what students must develop and what they must learn to abandon, this work enables educators to provide targeted support at the precise developmental moments when students need it most.

Understanding what students must develop alongside what they must shed enables educators to provide precisely timed support at critical developmental transitions. To empirically establish these ascending and descending trajectories, this study addresses two primary research questions:

1. What distinct developmental patterns emerge across the novice-to-expert continuum when epistemic codes are classified by their trajectory slopes?
2. How does the qualitative application of epistemic frames transform from second-year undergraduate students to practicing field professionals?

2. RELATED WORK

To understand how expertise develops, we must first understand what distinguishes experts from novices. Extensive research across multiple domains has documented systematic cognitive differences between expert and novice problem-solvers. Experts possess highly interconnected knowledge structures that support efficient chunking, reduce cognitive load. They can enable flexible, principle-based problem solving through forward reasoning and multiple solution pathways, along with extended reflection and evaluation [8, 9, 34, 50, 10, 39]. In contrast, novices rely on fragmented and superficial representations, they attend primarily to explicit problem features and known-unknowns rather than underlying principles, which limits transfer and strategy diversity [8, 9, 49, 40]. Novices predominantly employ means-end or backward inference strategies, resulting in trial-and-error approaches, minimal evaluation, and susceptibility to irrelevant information [34, 41, 26, 39, 38].

These expert-novice differences extend beyond problem solving. In categorization and representation tasks, experts emphasize deep structural relations while novices focus on surface or aesthetic features [25, 48, 31, 12]. This reflects the

role of tacit, experience-based knowledge in expert performance—knowledge that novices have not yet developed.

However, this cognitive divide is not a static binary state. Research across domains demonstrates that the sharp distinctions between expert and novice represent endpoints of a developmental continuum rather than discrete categories. Expertise emerges through gradual, qualitative transformation. The Dreyfus model captures this progression well, describing a move from rigid, rule-based reasoning (Novice) to context-sensitive, situational understanding (Expert) [13]. Similar developmental stages characteristics have been noted in medicine, where expertise emerges through iterative refinement of pattern recognition [4]. Yet recognizing that expertise develops along a continuum raises a fundamental question: what, precisely, is developing?

Expertise is more than cognitive transformation; rather, it is fundamentally multidimensional. Epistemic Frame Theory proposes that professional expertise emerges through the integration of five interconnected dimensions: Skills, Knowledge, Values, Identity, and Epistemology (SKIVE) [42, 45]. These dimensions do not develop in isolation, but they integrate into a cohesive professional lens over time. For an engineer, a design decision is never purely technical. It represents an interplay between technical knowledge, identity as a problem-solver, and values regarding system reliability and societal impact [42]. This EFT-grounded perspective fundamentally reshapes how we must study expertise development: rather than tracking a single cognitive trajectory, we must examine how all five SKIVE dimensions evolve simultaneously—and potentially at different rates.

Understanding this multidimensional development has important practical implications. This multidimensional view helps explain why engineering graduates struggle in professional practice despite strong technical performance in coursework [46, 51]. The transition from student to professional requires transformation not only in knowledge and skills, but also in values, identity, and epistemology. Without all dimensions developing in coordination, individuals may possess technical competence yet lack the integrated professional judgment required for effective practice. Understanding how this multidimensional development unfolds raises critical questions.

How do these dimensions develop across the undergraduate journey? When do specific transformations occur? Do all dimensions develop at the same rate, or do some lag behind? Most critically, does expertise follow only an upward trajectory of acquisition, or does it also require the active shedding of novice behaviors? Answering these questions requires methodological approaches that can capture the activation of knowledge, values, and identity as students engage with authentic professional tasks.

Think-aloud protocols (TAPs) offer one such approach. TAPs have long served as the gold standard for examining cognitive processes in expert-novice research [**?**]. In engineering education, these protocols provide a rich verbal trace of how students at different levels navigate design tasks, identify hidden constraints, and justify their actions through professional norms. While traditional observation only records what a student do, think-aloud protocols reveal the why exposing the activation of specific epistemic frame elements during problem-solving. When enhanced by eye-tracking data (ET-RTA) [37], these protocols provide even deeper insight into the cognitive processes underlying professional reasoning.

However, possessing a methodological tool does not guarantee a complete developmental picture. Existing research has documented endpoints of the expertise continuum such as novice versus expert characteristics, but provides limited insight into the developmental stages between them. We lack detailed understanding of the specific transformations that occur at each year of undergraduate training. We do not know which dimensions develop early and which lag behind. Crucially, we do not know whether expertise development is purely acquisitional or whether it also involves the strategic abandonment of novice strategies. Without this granular developmental map showing both what students must gain and what they must shed, educators cannot design stage-appropriate interventions or provide targeted scaffolding at the precise moments students need support.

This study addresses this gap by revealing the bidirectional nature of expertise development across the undergraduate-to-professional continuum. Through a cross-sectional design comparing second-year, third-year, and final-year students with practicing professionals on an authentic engineering task, we created a detailed benchmark of developmental characteristics at each stage. This benchmark reveals not only what grows but also what must be shed—providing the complete picture needed to design effective, stage-appropriate educational interventions.

3. METHODOLOGY

3.1 Study Design and Participants

This study employs a cross-sectional research design to capture the developmental trajectory of expertise from the undergraduate to professional practice. The study was conducted with 15 electrical engineering undergraduate students categorized by their academic level: Second-Year (SE, n=6), Third-Year (TE, n=5), Final-Year (BE, n=4), and an industrial expert (Exp, n=1). The industrial expert has been working in the power system grid industry for more than 15 years. This distribution enables a granular comparison of epistemic frame shifts across key curricular milestones. All procedures were approved by the Institutional Review Board (IRB), and informed consent was obtained from all participants for the use of their behavioral and verbal data.

3.2 The "Power to the People" game

Present research utilized "Power to the People," (developed by (https://www.rhombicogames.com), a high-fidelity power system role-playing game. This game requires participants to manage complex grid operations like optimization, load balance, mitigating faults, etc., as load demand of city expand dynamically. This environment provides a rich context for process mining, as it forces participants to move beyond theoretical knowledge to professional application.

3.3 Data Collection Method

Data collection was structured into three distinct phases designed to ensure data validity and minimize the novelty effect of the game interface:

Orientation and Familiarization (30-45 mins): To ensure that subsequent data captured cognitive processes rather than interface-learning hurdles, participants underwent a standardized demo and checklist-driven practice. They practiced installing substations and managing generators in a neutral simulation environment ("Siem Reap, Cambodia").

Gameplay and Gaze Capture (30-40 mins): Participants transitioned to the experimental task centered on the "Agra, India" city layout. During this phase, a Tobii Pro Nano (60 Hz) eye tracker was used to record eye-gaze data. This eye-tracking layer serves as a digital trace of the participant's visual attention, providing a non-intrusive log of their interaction with the grid.

Eye-Gaze Enhanced Retrospective Think-Aloud (ET-RTA): Post-gameplay, we conducted structured interviews (average duration 70-80 minutes) using the ET-RTA protocol. Participants viewed their gameplay video overlaid with their gaze plots, which served as a cued-recall stimulus. This method allows the extraction of rich process level verbal protocols grounded in actual behavioral traces, reducing the risk of post-hoc rationalization [37].

3.4 Data Transformation and Coding

To bridge the gap between qualitative learning sciences and quantitative data mining, our approach treats unstructured verbal data as a source for computational modeling. This study employs a data processing pipeline that transforms coded verbalizations into normalized feature vectors. By calculating the slope of these vectors across academic cohorts, we establish a mathematical framework for mining the trajectories of expertise development. This methodology aligns with the EDM community's focus on modeling complex learner behavior through reproducible, quantitative metrics.

The recorded ET-RTA interviews were transcribed and analyzed using a hybrid coding approach. We employed the EFT framework deductively to categorize broad epistemic codes, while inductively deriving sub-codes like $S.Monitoring$, and $E.Real.Life$ etc. from the verbal data. The detailed codebook is available **here**. The reliability of coding was assessed using Cohen's kappa (κ) as a measure of inter-rater reliability. In the first round, two independent educational technology researchers coded 30% of the interview responses. This was followed by a second round of discussion to resolve disagreements and establish consensus. All codes demonstrated a high level of agreement between coders ($\kappa = 0.80$). This value indicates substantial inter-rater agreement [33] suggesting that the coding procedures were reliable across constructs.

The resulting dataset was normalized by calculating the relative frequency of codes per cohort (see section 4), enabling a quantitative analysis of the expertise trajectory, shifting the focus from qualitative description to data-driven pattern recognition.

4. ANALYSIS

To investigate the developmental trajectory of expertise, this study employs a cross-sectional quantitative design. By comparing four cohorts: second-year, third-year, and final-year undergraduate students, alongside practicing professional, we construct a developmental benchmarks representing distinct stages of professional growth. This approach allows us to identify patterns of expertise development across the undergraduate-to-professional continuum.

The challenge in analyzing the cross-sectional datasets is that code frequencies often exhibit extreme variance. Verbal protocols often generate massive amounts of unstructured data that are difficult to compare across different levels of expertise. A significant hurdle we encountered in this process was the natural variation in participant verbosity; for instance, a talkative novice might produce a higher raw frequency of codes than a concise expert, potentially skewing the developmental signal. In raw frequency analysis, the visual prominence of a code is strictly determined by its cumulative count [47]. This creates a visual flattening effect for lower-frequency codes. For example, if a skill code $.Troubleshooting$ appears 50 times and an epistemology code $E.Design$ appears 5 times, the graphs will be dominated by the skill code, and the visuals will be very flat for the epistemology code. In a standard line chart, the $S.Troubleshooting$ line will oscillate high on the Y-axis, whereas the $E.Design$ line, even if it triples from 2 to 6 mentions (a 200% growth), will appear as a nearly flat line at the bottom of the chart. One might visually conclude that nothing happened with the epistemology code, simply because its geometric slope is dwarfed by the magnitude of the skill code.

4.1 Two-Step Normalization Procedure

To enable fair comparison across cohorts despite both unequal sample sizes and scale differences, we employed a two-step normalization procedure.

Step 1: Group Averaging: To neutralize the influence of cohort size (SE=6, TE=5, BE=4, Exp=1), we first calculated group-averaged frequencies by $\bar{X}_{SE} = \sum X_{SE}/6$, $\bar{X}_{TE} = \sum X_{TE}/5$, $\bar{X}_{BE} = \sum X_{BE}/4$, and $\bar{X}_{Exp} = \sum X_{Exp}/1$. This yields a single representative value per code per stage.

Step 2: Min-Max Normalization: Even after group averaging, codes exhibit extreme variance in absolute magnitude (e.g., high-frequency $S.Troubleshooting$ vs. low-frequency $E.Design$.To address this, we applied standardization techniques such as min-max normalization to systematically transform these narratives into a quantifiable dataset. Min-max normalization as shown in equation 1 [21] standardizes the dataset, ensuring that all features contribute proportionately to the final result. By placing all data points on a common scale, we could exclude the impact of outliers on their broader conclusions [5, 47].

Let $C_{i,t}$ denote the averaged raw frequencies of code i at developmental stage t, where $t \in \{\text{SE}, \text{TE}, \text{BE}, \text{Exp}\}$. The normalized weight $W_{i,t}$ is calculated as:

$$W_{i,t} = \frac{C_{i,t} - \min(C_i)}{\max(C_i) - \min(C_i)} \quad (1)$$

where $\min(C_i)$ and $\max(C_i)$ represent the minimum and maximum frequencies of code i observed across the four temporal stages.

This transformation maps each code's emphasis to the unit interval $[0, 1]$. A value of 1 indicates the stage of maximum relative emphasis, while 0 indicates the minimum. By scaling the raw frequencies into a standardized range $[0, 1]$, we were able to conduct a fair comparison of all the code elements across the second-year (SE), third-year (TE), final-year (BE), and expert groups, regardless of their total word count. This mathematical adjustment was central to our study, as it enabled us to visualize and quantify the movement of expertise. Specifically, it allowed us to model the expertise continuum as a series of developmental trajectories. The normalized values of all the codes helped us to plot the trajectories of all the codes as shown in Figure 1.

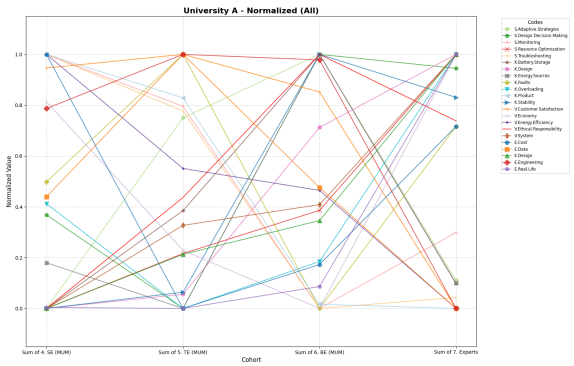

Figure 1: Developmental Trajectories of epistemic codes using min-max normalization

4.2 Slope

Figure 1 shows the trajectories of all the codes across cohorts, but to quantify the directional magnitude of each code, we derived a slope for each trajectory. This slope represents the mean rate of shift from the novice state (SE) to the expert state (Exp). Given that the timeline consists of four distinct stages (SE, TE, BE, Exp), the slope is defined as the total normalized displacement averaged over the temporal span:

$$\lambda_i = \frac{W_{i,\text{Exp}} - W_{i,\text{SE}}}{3} \quad (2)$$

The resulting λ_i values range from -0.33 (a complete shift from maximum usage at SE to minimum usage at Expert) to $+0.33$ (the inverse). The overall range of the λ_i values is therefore 0.66.

4.3 Statistical Thresholding and Classification

To categorize the diverse trajectories into meaningful epistemic patterns, we established a slope-based threshold τ to distinguish substantive developmental trends from transitional volatility.

An analysis of the distribution of slopes across the combined dataset for all $N = 44$ across 22 unique codes revealed a mean of $\mu = 0.02$ and a standard deviation of $sd = 0.24$. To ensure robustness in identifying distinct developmental trajectories, we selected a threshold of $\tau = \pm 0.15$, derived from the data distribution and focused on quartile alignment (see Figure 2). Specifically, this threshold approximates the absolute boundaries of the interquartile range (IQR = 0.42, spanning Q1 ≈ -0.17 to Q3 $\approx +0.25$): the negative threshold (-0.15) is close to Q1 (capturing the lower quartile's tail for negative shifts), while the positive threshold ($+0.15$) falls between the median (Q2 ≈ 0.02) and Q3 (highlighting the upper quartile for positive shifts). This approach effectively filters out central noise within the IQR, ensuring the classification prioritizes the most pronounced shifts in the outer quartiles while accounting for the distribution's slight positive skew.

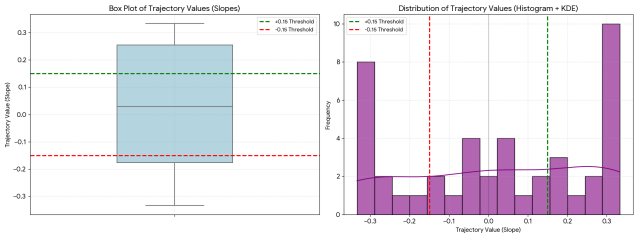

Figure 2: Statistical distribution of trajectory slopes (λ) for all codes. (Left) Box plot displaying the Interquartile Range (IQR) with Q1 ≈ -0.17 and Q3 ≈ 0.24. The dashed lines at ± 0.15 align closely with these quartiles, justifying their use as discriminatory thresholds. (Right) Histogram. The red (-0.15) and green ($+0.15$) thresholds clearly separate the central "transitional" bell curve from the significant negative and positive tails (Major Decline and Major Growth).

Using $\tau = 0.15$, we categorized the epistemic trajectories into four distinct types as shown in Table 1.

Table 1: Threshold Value Range for Categorizing Trajectory Types

Trajectory Type	Mathematical Definition
Type 1: Major Growth	$\lambda_i > +0.15$
Type 2: Minor Growth	$0 < \lambda_i \leq +0.15$
Type 3: Minor Decline	$-0.15 \leq \lambda_i < 0$
Type 4: Major Decline	$\lambda_i < -0.15$

4.4 Integration of Qualitative Protocol

To interpret the trajectories derived from the slope-based classification, we employed a qualitative approach. While the quantitative metrics (slope λ) identify which behaviors change, they do not explain how the nature of that behavior transforms. Therefore, we aligned the normalized code weights (W_i) with their corresponding verbal protocol segments. For each significant trajectory, we conducted a the-

matic analysis of the excerpts to extract the semantic and cognitive shifts driving the statistical trend, ensuring that every quantitative claim is grounded in participant evidence.

5. RESULTS

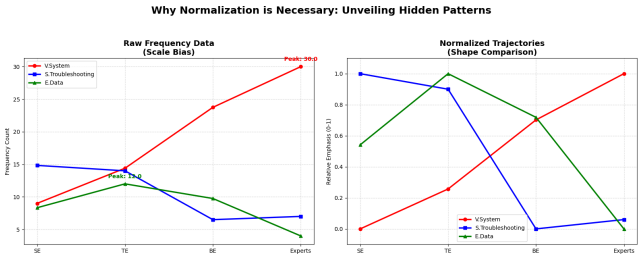

Figure 3: Comparative plots of raw frequency (left) and normalized trajectories (right) for selected codes: V.System, S.Troubleshooting, and E.Data.

To illustrate how normalization helps visualize epistemic trajectories, we compare the raw and normalized distributions of three representative codes: *V.System* (Values: System Stability), *S.Troubleshooting* (Skills: Troubleshooting), and *E.Data* (Epistemology: Data-driven Justification) (Figure 3). The raw frequency graph (left) exhibits a significant scale bias, where high-volume codes like *V.System* (RED) peaking at ≈ 30, exerts a magnitude bias that suppresses lower-frequency codes like *E.Data* (GREEN). *E.Data* is less frequent peaking at ≈ 12 and appears flat across the four cohorts. If we have to make the inference from this, the development across the 4 cohorts will be stagnant when viewed on a shared raw axis with *V.System*.

In contrast, the min-max normalized graph (right) performs a crucial analytical equalization. By scaling each trajectory independently to a standardized $[0, 1]$ range, we eliminate verbosity-induced noise and reveal the relative intensity of each epistemic element within its own developmental lifecycle. This transformation allows the trajectories' distinct shapes to emerge as the primary visual feature. We can now observe, for instance, that while *S.Troubleshooting* (BLUE) might have a high raw volume in the sophomore year, its relative importance to the expert's frame is negligible compared to the sharp uptrend of *E.Data*. Without this normalization, our analysis would be trapped in a frequency bias, leading to erroneous conclusions. Such as certain professional traits are absent simply because they are spoken with more precision and fewer words. Normalization thus serves as a lens that brings the structure of the epistemic frame into focus, allowing us to quantify the movement of expertise across the continuum with mathematical parity.

5.1 RQ1

What distinct developmental patterns emerge across the novice-to-expert continuum when epistemic codes are classified by their trajectory slopes?

Following the application of min-max normalization, we performed a slope-based classification to categorize the developmental trends across 22 codes. Utilizing the thresholds defined in Table 1, four major trajectories of the movement of epistemic frames across the four cohorts emerged. These trajectories are linear (Type 1: Major Growth; Type 4: Major Decline) and non-linear (Type 2: Minor Growth; Type 3: Minor Decline) (Figure 4.)

The sequence of normalized weights W_i corresponding to each trajectory is presented in Table 2.

Table 2: Sequence of the SE, TE, BE, Exp weights in four trajectories

Trajectory Type	Sequence of normalized weights	Shape of the Trajectory
Type 1: Major-Growth	$W_{\text{SE}} < W_{\text{TE}} < W_{\text{BE}} < W_{\text{Expert}}$	Uptrend
Type 2: Minor-Growth	$W_{\text{SE}} < W_{\text{TE}} \leq W_{\text{BE}} > W_{\text{Expert}}$	Hump
Type 3: Minor-Decline	$W_{\text{SE}} > W_{\text{TE}} \geq W_{\text{BE}} < W_{\text{Expert}}$	Dip
Type 4: Major-Decline	$W_{\text{SE}} > W_{\text{TE}} > W_{\text{BE}} > W_{\text{Expert}}$	Downtrend

In this paper, we focus our analysis exclusively on the two most significant graphs: *Type 1 (Major Growth)* and *Type 4 (Major Decline)*. Type 1 (Major Growth: Uptrend): These trajectories represent "expert-like" competencies that show a consistent increase in relative intensity as students move toward professional practice. Type 4 (major Decline: Downtrend): These trajectories represent "novice-heavy" habits that are systematically abandoned or automated as expertise develops.

We have intentionally excluded Type 2 and Type 3 from the current discussion. These categories exhibit high intra-group volatility, characterized by non-linear fluctuations such as "humps" (peaks at TE or BE) and "dips" (Dips at TE or BE). In the context of trajectory modeling, these volatile patterns often contain a high degree of statistical noise or represent complex, intermediate cognitive restructuring that requires a more granular longitudinal analysis. Therefore, the detailed examination of these fluctuating patterns is beyond the scope of this paper.

5.2 RQ2

How does the qualitative nature of epistemic frames evolve from Second-Year students to practicing professionals?

This section talks about the two primary developmental trajectories: *Type 1 (Major Growth)* and *Type 4 (Major Decline)* revealed through the application of min-max normalization and slope-based classification. For each trajectory, we present the quantitative findings followed by a qualitative analysis of representative excerpts. This mixed-methods structure allows us to demonstrate not only the statistical magnitude (through W_i) of the change but also the qualitative evolution of the learner's reasoning strategies from the Second Year (SE) to the Expert level.

5.2.1 Type 1: Major Growth: Uptrend

Figure 5 shows the type 1 trajectory with the slope $\lambda \geq +0.15$. This Trajectory represents the acquisition of high-level professional frames. The key codes that are under are:

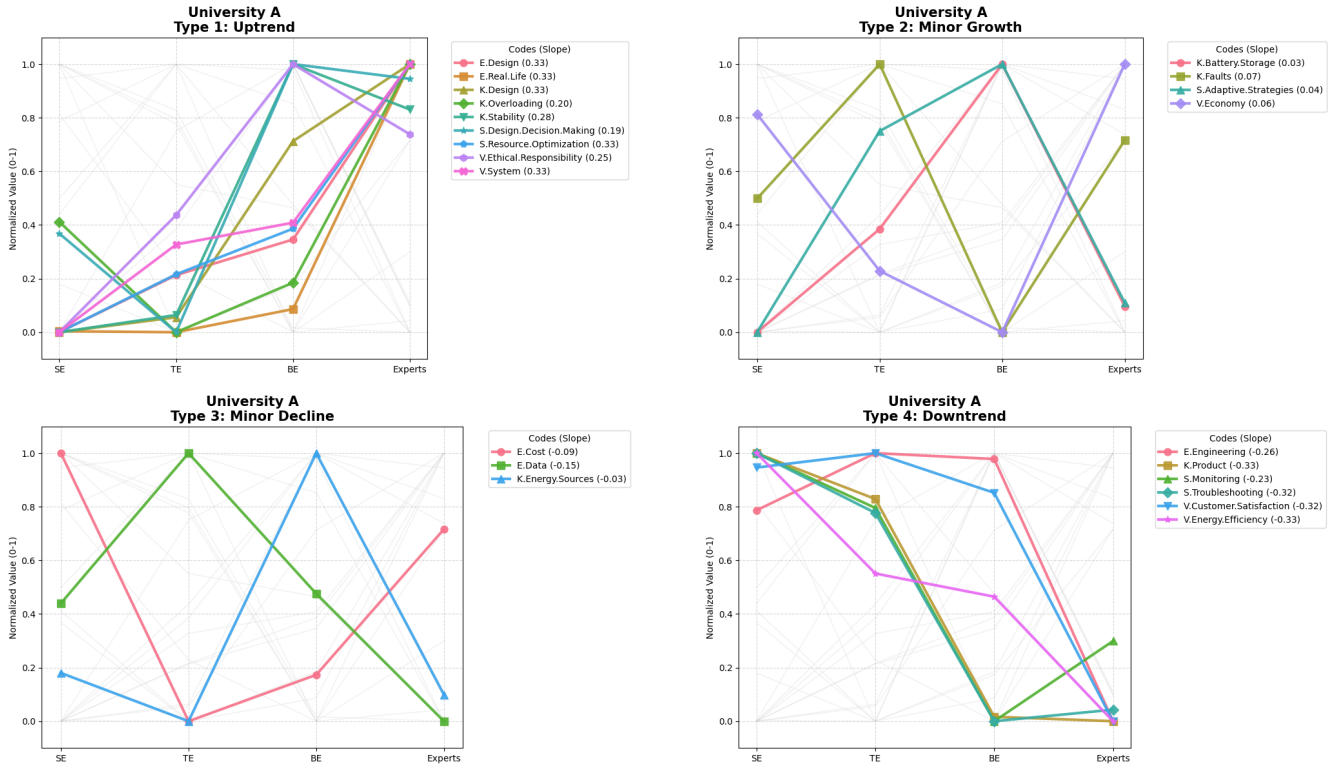

Figure 4: Classification of trajectories into four types with respect to slope threshold (± 0.15).

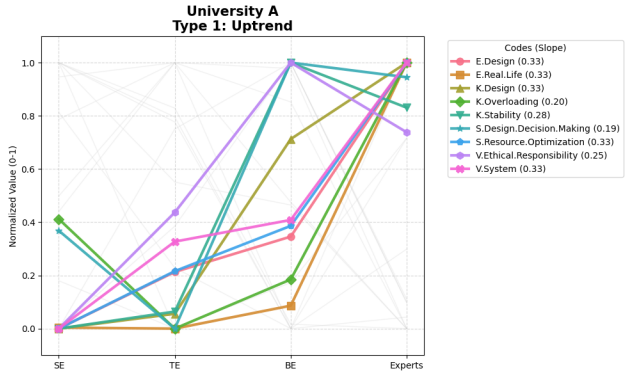

Figure 5: The Ascending Trajectory of epistemic frames with $\lambda \geq +0.15$.

- E.Design: 0.33
- E.Real.life: 0.33
- K.Design: 0.33
- K.Overloading: 0.20
- K.Stability: 0.28
- S.Design.Decision.Making: 0.19
- S.Resource.Optimization: 0.33
- V.Ethical.Responsibility: 0.25
- V.System: 0.33

These codes exhibit a consistent increase in normalized weight from the Second Year (SE) to the Expert (EXP). The sequence of the weights W_i for this Type 1 trajectory can be seen Table 2 in row 1, signaling the successful adoption of the learner into the community of practice.

E.Real.Life ($\lambda = 0.33$): It is the most significant developmental signal observed in Uptrend. The trajectory reveals a late-blooming pattern where the code is virtually flat in SE (0.0) and TE (0.12) cohorts, reflecting an academic isolation where real-world constraints are invisible to the student. A noticeable shift occurs in the BE cohort (0.58), but the Expert cohort reaches saturation (1.0). Qualitative analysis shows that Experts exclusively use field heuristics. Experts replace theoretical citations with professional intuition. As one expert noted, *"In a real grid, you utilize diversity factors... you don't design for the peak of every single house simultaneously."*. This expert behavior shows the effective replacement of the classroom lens of the novice with the field lens of the practitioner.

S.Design.Decision.Making ($\lambda = 0.19$): This epistemological shift is mirrored in the evolution of design logic, revealing a four-stage maturation moving from surface heuristics to deep structural analysis. Novices (SE) initially relied on cost and quality heuristics, operating on the naive assumption that price equals quality. As one student noted, *"I thought the more expensive the thing, the better. So I bought it... I thought it would be better if the cost was higher."* This

indicates a decision-making process driven by budget variables rather than technical fit. By the Third Year (TE), this evolves into Attribute Matching, where students align static component features with spatial needs. For instance, a TE student stated, *"...because this city is small. So I have used a small local substation."* While logical, this approach remains static and spatial. A higher-order complexity emerges in the Final Year (BE), characterized by Multi-Variable Analysis. These students balance conflicting variables like terrain, weather data, and future load before execution. An excerpt illustrates this data-driven approach: *"I looked at precipitation graphs... we have a lot of precipitation... I looked at the terrain where I can see that there are some places where we have trees."* Finally, Experts transcend the game's explicit variables to incorporate Real-World constraints that are invisible in the game interface. They describe the grid's topology before placing a single component, noting, *"First, I am identifying the load centers... the ring main unit will provide redundancy here before I even connect the generation."* The expert protocol reveals a distinct pre-design phase absent in novices, in which contingencies for future load growth are calculated before implementation.

V.System ($\lambda = 0.33$):The data further highlights a transformation in how participants define value, specifically capturing the prioritization of grid stability. In the SE cohort, this value appeared frequently but was framed negatively in terms of the avoidance of game penalties, with students noting, "I removed the line because the message came." By the Expert phase, the normalized frequency remained high, but the definition of the system changed from a set of game rules to an internalized standard of care. They impose an intrinsic benchmark of system health that dictates grid robustness, regardless of whether the external agent explicitly penalizes them or not. An expert illustrates this internalized standard, stating, "I try to keep the system healthy... If there is a breakdown, how to restore it immediately, how to stay healthy, we work from this perspective..." This reflects a shift in role identity from a builder following instructions to a guardian of continuity.

V.Ethical.Responsibility ($\lambda = 0.25$): Concurrently, this trajectory tracks the expansion of the moral boundary. Novices (0.20) framed ethics transactionally, viewing the utility to customer relationship as a commercial contract for profit. One SE student explicitly stated, *"ofcourse, Customer satisfaction is my priority... if I promise that I will give this to customers, I will give it first... that will give me profit..."* This perspective shifts toward environmental stewardship in the Final Year (BE). These students are willing to sacrifice economic efficiency to protect the aesthetic and environmental integrity of the region. A final-year student noted, *"Also coal... of course it's cost is less, but over the longer period of time it will get extinct. And also there will be a lot of pollution and if this polluted air gets to Taj Mahal of course there will be consequences to its beauty..."* Finally, values shift to a non-negotiable civic duty for Experts (1.0), who feel it is the fundamental purpose of their profession. The expert views the grid not as a commercial asset, but as a public utility essential for life. Stripping away all complex variables, one expert revealed the singular mission of the grid: *"We just want the system to deliver electricity to every consumer. That's all we want. We work from this perspective."* This indicates that universal accessibility is the foundational axiom of their mental model, creating an obligation to serve everyone regardless of difficulty.

S.Resource.Optimization ($\lambda = 0.33$): Finally, this trajectory tracks the sophistication of efficiency strategies. SE novices employed naive spatial symmetry, such as "splitting the load 50/50" based purely on visual geometry. One SE student explained, *"I will give an even distribution. If there are 100 residents, 50 will be distributed by one line and 50 by another line. So that the load on the line will be less. I have split it like that."*. TE students advanced to component-level optimization (e.g., matching a small substation to a small city), reflecting a textbook understanding of capacity. However, the trajectory peaks as Experts integrate complex variables—cost, line loss, and future demand—into a single decision matrix. Experts demonstrate a well-thought-out optimized system, with reasoning well grounded in real-world practices. Continuously reflecting on field experience, an expert noted, *"The installed capacity must be higher than the requirement. So, I was thinking of the maximum install capacity power plant...I learned from that practical experience that segregation of equal loading is very much insufficient."*

5.2.2 Type 4: Major Decline: Downtrend

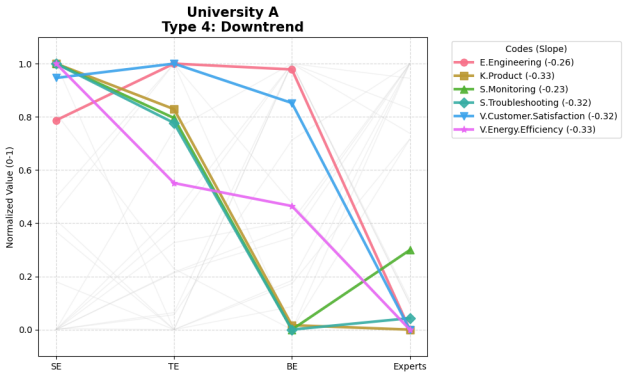

Figure 6: The Descending Trajectories of Cognitive Automation ($\lambda \leq -0.15$)

Figure 6 shows the type 4 trajectory with the slope $\lambda \leq -0.15$. This trajectory represents the fading away of the novice habits. The sequence of the weights W_i for this Type 4 trajectory can be seen Table 2 in row 4. This decrease in weights W_i are critical as they identify behaviors that are prominent in novices(SE) but recede as expertise develops (Exp). This trend does not indicate skill loss, but rather the *cognitive automation* of foundational processes.

The Type 4 trajectories ($\lambda \leq -0.15$) exhibited a negative slope. The key codes fall under:

- S.Troubleshooting (-0.32)
- S.Monitoring (-0.23)
- V.Customer.Satisfaction (-0.32)
- K.Product (-0.33)
- V.Energy.Efficiency (-0.33)

- E.Engineering (-0.26)

S.Monitoring ($\lambda = -0.23$):The most dramatic decline was observed in this trajectory, which captures the reliance on visual verification. SE participants recorded the highest weight (1.0), primarily associated with surface monitoring (constantly scanning the interface for color-coded warnings). An SE student noted, *"I am checking the red line... it turned red again."* This reflects a reactive stance where the student awaits visual feedback from the game mechanics to validate the grid's state. In contrast, Experts (< 0.1), possessing a proactive mental model. Experts analyse the load distribution internally before placement. Consequently, the need for explicit verbal monitoring vanishes; they trust their internal simulation, whereas the novice requires constant external validation.

S.Troubleshooting ($\lambda = -0.32$): Similarly, this trajectory tracks the shift from a trial-and-error loop of patching crashes to a proactive design strategy. Novices (SE) explicitly described a reactive dependency on game notifications, stating, "I got the message twice. I removed them as the message came... Because the last time was short circuit. I wish there was a help button... I thought I was doing it wrong and that's why he is giving me notice." When Third-Year (TE) students encounter errors, they understand the underlying reasons but still perform actions strictly by the rules, indicating a transitional learning phase. A qualitative leap occurs in the Final Year (BE), where students stop reactive error fixing and start simulating alternative strategies to prevent errors entirely. As one BE student explained, "I would have added wind turbine if there was some height. this is like, you know, just alternative way..." This marks the transition to a proactive design strategy that resolves contingencies upfront, eliminating the need for reactive fixes.

The interesting finding for this code is, as expertise develops, this code vanishes. In opposition to the students, the Expert starts designing the grid for reliability and, as they do so, accounts for contingencies. The contingency-oriented behavior can be seen through *"..whatever the fault occurs further, lets say this point, is prone to the overloading, we can have one fault, but as I have this one substation, it is backup for me. So that I can distribute power properly or evenly to particular area..."*. This expert's behavior is typically because they employ a well-thought-out plan in advance.

K.Product ($\lambda = -0.33$):A similar trend characterizes a shift from declarative labeling to tacit integration. The data shows a monotonic decline from SE (1.0) to Expert (0.0). SEs record the highest weight because they must explicitly verbalize their understanding of surface features, often appearing overwhelmed by game mechanics. An SE student noted, *"...I chose a wind turbine, but I didn't get the output... I thought maybe it's a problem with wind or connection maybe..."* This excerpt highlights a focus on the object itself rather than the underlying reason for its failure. In the intermediate phases, the nature of knowledge becomes procedural. While TEs and BEs still frequently reference product names, they begin to connect these labels to broader concepts, attaching conditions and rules to facts. They select objects based on specific conditions rather than just availability. The Expert, conversely, invokes the tacit professional world—referencing concepts like Site Survey and Load Center—that precedes the product. The quantitative drop signifies that the game interface has become transparent; they think through the component to the solution. For the professional, the wind turbine is not a standalone object to be bought, but a conditional solution that emerges from a rigorous assessment. As one expert explained, *"So, in real life, there are many more constraints... we do site survey, we do load center survey... If it is in hilly areas, with good wind speed, we go for wind power turbines... If it is near to the coal mines... we go for coal..."* The expert zooms out beyond the game graph to reference the site survey protocol.

E.Engineering ($\lambda = -0.21$): An interesting deviation from the linear downtrend was found in this trajectory, which followed an inverted-U shape. It peaked in the Third Year (TE) (1.0), reflecting a cohort immersed in heavy theory ("Power Systems I"). TEs attempted to force complex academic constraints, such as per-unit systems or reactance values, onto the game to validate their knowledge. As one TE student noted, *"I was thinking about the 'per-unit' system... to see if the game follows the standard reactance values."* Strikingly, the Expert cohort dropped to zero. Experts did not cite academic theories, voltage or current Laws, or even Electricity Rules by competent authorities, because these norms are internalized and hence tacit. This finding suggests a theoretical trap in the TE year that must be transcended to achieve professional fluency.

V.Energy.Efficiency ($\lambda = -0.33$) along with *V.Customer.Satisfaction* ($\lambda = -0.22$): Lastly, value-based codes showed marked declines. Novices verbalized these as distinct, affective goals, often worrying about "sad people" or "happy faces" on the interface. For experts, these are not separate values to be maximized but embedded constraints within the primary goal of *V.System*; they do not speak of efficiency separately because a stable grid is inherently efficient. The disappearance of these explicit codes marks the transition from explicit student values to implicit professional norms.

6. DISCUSSION

This study aimed to map the granular developmental trajectory of electrical engineering expertise. By quantifying the shift in epistemic frames from the Second Year (SE) to the Expert level, our results provide the empirical evidence for the traditional accumulation model of expertise. The data reveals that expertise development is not merely a linear addition of technical skills, but a complex, trajectories: the simultaneous Adoption of a Professional Lens (Ascending Trajectories) and the Shedding of Novice Habits (Descending Trajectories). This section discusses the mechanisms driving these patterns.

6.1 Adoption of a Professional Lens: Game Rules to Professional lens

The ascending trajectories of *E.Real.Life* and *V.System* illustrate a fundamental shift in the learner's Locus of Control. Novices (SE) operate within an academic frame, where value is defined externally by game mechanics or grading rubrics. This aligns with Engstrom's [14] distinction between school-going activity, where the object is the grade, and work activity, where the object is the societal value.

Their high frequency of *V.System* indicates a defensive mechanism, they act to avoid error messages rather than to ensure system health.

In contrast, the Expert frame is driven by an Internalized Standards. The synchronization of *V.System* and *V.Ethical.Responsibility* in the expert cohort suggests that for a professional, technical decisions are inseparable from their social consequences. This confirms Shaffer's [44] core tenet that professional expertise is not just "knowing how" (Skills) or "knowing that" (Knowledge), but "knowing with" adopting the values and identity of the community of practice. This trajectory reflects Lave and Wenger's [35] theory of Legitimate Peripheral Participation: novices remain on the periphery of the engineering community, engaging academic problems without context, while experts demonstrate full participation through internalized professional values and identity. The delayed emergence of *V.Ethical.Responsibility* codes suggests that undergraduate curricula provide limited opportunity for authentic engagement with the community of practice where these dimensions are enacted [52]. The delayed emergence of these codes points to a critical gap in the curriculum. While students acquire technical competence early, they suffer from contextual isolation, lacking the situated learning environment described by Lave and Wenger [35]. They possess the syntax of engineering (the math) without the semantics (the professional meaning). The sharp rise in the Expert cohort confirms that true fluency requires the adoption of this professional lens. This is a process that currently appears to happen largely after the graduation.

6.2 Shedding Novice Habits: From Reactive Monitoring to Proactive Design

The steep decline in *S.Monitoring* and *K.Product* highlights the mechanism of how novices display a high interaction with game interface, constantly verbalizing labels and verifying visual feedback from the system. They constantly verbalize component labels and verify visual feedback, outsourcing working memory to external representations—a phenomenon known in cognitive science as distributed cognition [29]. This external scaffolding is necessary and adaptive at early stages; without robust internal models, novices require the interface to confirm their understanding at each step.

However, the persistence of these behaviors in third-year (TE) and final-year (BE) students signals problematic dependency. This reflects what Braver [6] terms reactive control: students respond to feedback rather than anticipating consequences beforehand. They rely on the interface to tell them whether a design works, treating error messages as cues to act upon rather than using principled reasoning to avoid errors in the first place. While *S.Design* was visible in their protocols, it lacked correlation with *K.Design* and *E.Design* novices were mimicking engineering actions without the supporting epistemic structure to predict outcomes.

In contrast, experts demonstrate proactive control [6, 30], they simulate outcomes internally before acting. The expert's relative silence during problem-solving is not an absence of cognition but evidence of internalized mental models. The epistemic frame has become so compressed that intermediate reasoning steps no longer require conscious verbalization or external verification. Experts have effectively shed the scaffolding behaviors that once supported their learning, achieving what Dreyfus and Dreyfus [13] describe as the fluid, intuitive performance of expertise—no longer relying on context-free rules or external feedback but on internalized professional judgment.

6.3 The "Theoretical Frame": The Intermediate Effect

An interesting finding was the trajectory of *E.Engineering*, which peaked in the Third Year (TE). This aligns with the intermediate effects observed in medical education by Schmidt and Rikers [43], where intermediate learners process information more laboriously than both novices and experts due to the activation of elaborate but encapsulated causal networks. The TE cohort, immersed in heavy theory courses, attempted to force rigid academic abstractions e.g., ($Per - UnitSystems$) onto a dynamic problem where they were ill-suited. This represents rigidity of the academic, as there is more emphasis on theoretical precision (*E.Engineering*) that temporarily overrides practical intuition (*E.Real.Life*). If not corrected, this leads to graduates who are technically rigorous but practically paralyzed. The drop to near-zero in the expert cohort confirms Glaser's [23] observation that expertise relies on flexible, context-sensitive heuristics rather than the rigid application of weak methods.

6.4 The Expert as Benchmark

A key methodological consideration in this study concerns the asymmetric sample composition, particularly the inclusion of a single expert participant. While this represents a limitation in terms of statistical generalizability, the design employs the expert not as a representative mean but as "a gold standard benchmark". This methodological approach aligned with Epistemic Frame Theory's use of professional exemplars to define the target epistemic state toward which learners progress [44]. This benchmark serves to identify the "ceiling" of the professional lens, establishing the developmental endpoint against which student trajectories can be mapped.

The resulting trajectories reveal systematic patterns: ascending codes (e.g., *E.Real.Life*, *V.Ethical*) show consistent growth from SE through Expert, while descending codes (e.g., *S.Monitoring*, *K.Product*) demonstrate systematic decline. These patterns emerge not from statistical aggregation across multiple experts, but from the structural positioning of student cohorts relative to the professional benchmark. The consistency of these trajectories across multiple SKIVE dimensions—with some ascending, some descending, and some exhibiting non-linear patterns—suggests that the observed trends reflect genuine developmental phenomena rather than artifacts of individual expert variation.

7. CONCLUSION AND IMPLICATIONS

This study highlights the holistic nature of the expertise gap: students do not primarily lack knowledge; rather, they operate within a fractured epistemic frame in which theory, design, and ethics are treated as separable academic tasks. In contrast, expert practice reflects a comprehensive epistemic frame, in which technical reasoning, ethical judgment, and contextual awareness are inseparable and enacted simultane-

ously through an internalized professional lens. By applying min-max normalization to verbal protocols, we effectively neutralized the verbosity bias that often obscures qualitative comparisons. This methodological innovation allowed us to visualize expertise as two simultaneous trajectories: the *Adoption of Professional lens* (Uptrends) and the *Shedding of Novice Habits* (Downtrends). Our analysis confirms that the silence of an expert is as significant as the speech of a novice. The monotonic decline of codes like *K.Product* and *S.Monitoring* provides empirical evidence that expertise involves the internalization of rules. Conversely, the ascent of *E.Real.Life* and *V.System* maps the transition from a reactive, rule-based game lens to a proactive, ethical field lens.

The revealed trajectories provide actionable insights for curriculum design, specifically for bridging the gap between academic theory and professional practice. The late emergence of *E.Real.Life* suggests that current curricula may isolate students in academic idealism for too long. To accelerate novices' development toward expert-like competencies, programs should integrate real-world constraints. The trajectory of *V.Ethical.Responsibility* implies that ethics training must evolve. Rather than treating ethics as a separate compliance module, it should be embedded in technical design tasks.

8. LIMITATIONS AND FUTURE WORK

We acknowledge that the single-expert (n=1) limits claims about variability in expert performance across engineering sub-domains or institutional contexts. Future work should expand the expert cohort to examine whether these trajectory slopes remain stable across diverse professional populations. Such expansion would enable investigation of whether the professional lens exhibits domain-specific variations or represents a more universal engineering epistemic frame. Nevertheless, the current benchmark approach provides sufficient granularity to identify which expert-like competencies emerge at which undergraduate stages and which novice behaviors require explicit intervention—actionable insights that inform curriculum design even in the absence of expert population statistics.

Additionally, the cross-sectional design infers developmental trajectories rather than tracking them directly. Future research should employ longitudinal designs to validate whether individual learners typically traverse these inferred paths. Furthermore, to empirically triangulate the phenomenon of "expert silence" (specifically in *S.Monitoring*), future work will integrate Multimodal Learning Analytics (MMLA).

ABSTRACT
Pattern mining techniques are widely used in Educational Data Mining to uncover meaningful patterns in learner behaviors, discourse, and learning processes. However, a range of metrics is used to quantify pattern strength, often producing different conclusions. In this study, we systematically compare popular metrics from Association Rule Mining, Sequential Pattern Mining, Epistemic Network Analysis (ENA), and Ordered Network Analysis (ONA) by examining (a) similarities in the patterns highlighted by each method and metric, (b) their associations with validated external measures of learning and motivation, and (c) expert ratings of theoretical alignment and perceived interestingness. Our results reveal two clusters of metrics: one emphasizing frequent, common, and theoretically expected patterns (*Support, Confidence, Cosine, Jaccard*, and *ENA/ONA connection weights*), and another emphasizing less frequent patterns driven more by statistical dependence than by prevalence (e.g., *Added Value, Conviction*, the *Phi coefficient*, and *Lift*). This second group is sometimes rated as more interesting but is less theoretically aligned. Our findings suggest that combining multiple metrics and methods can provide complementary perspectives, either reinforcing conclusions when results converge or signaling the need for deeper investigation when they diverge. Doing so can help us to better understand complex learning processes and their relationships with educational outcomes.

Association Rule Mining, Sequential Pattern Mining, Epistemic Network Analysis, Ordered Network Analysis, Interestingness Metrics.

1. INTRODUCTION
A strength of the Educational Data Mining (EDM) community is the diverse range of modeling approaches and algorithms it employs, often to study the same phenomena. One area where this is the case is pattern mining techniques such as Association Rule Mining (ARM; [1]), which have been widely applied to uncover interpretable patterns in student behaviors, problem-solving actions, and learning processes [11, 20, 22, 24].

ARM techniques aim to identify implication rules of the form X→Y that capture relationships among events, items, or discrete variable values based on their co-occurrence in data [1]. To achieve this, ARM employs a range of methods to mine potentially meaningful patterns [21], along with metrics to assess which patterns merit further analysis or consideration [19, 33]. Each of these metrics emphasizes different aspects of these patterns, such as their frequency (*Support*) or conditional reliability (*Confidence*). Others highlight associations that deviate from expectations under statistical independence (*Lift and Cosine*) and capture the extent to which the occurrence of one event increases the likelihood of another beyond its base rate (*Added Value*). The choice of metric influences which patterns are identified and how they are interpreted, particularly in applied domains such as EDM, where interpretability and relevance to learning processes are central.

More recently, Epistemic Network Analysis (ENA; [27]) has emerged as an alternative approach for discovering important relationships between discrete variable values. Initially developed to study thematic complexity in discourse data, ENA models learning processes by counting patterns of co-occurrence and applying cosine normalization (distinct from the *Cosine* similarity metric used in ARM) to estimate the strength of connections between codes, while accounting for differences in discourse length or interaction volume across the students or groups being analyzed [7, 27]. A key strength of ENA lies in its network representations, which support visual interpretation of complex relationships among codes and facilitate exploratory analyses of learning processes. However, the quantification of ENA patterns is typically achieved by comparing its *Connection Weights*, which are conceptually similar to ARM's *Support*. Unlike other ARM metrics such as *Cosine*, *Lift*, or *Added Value*, *ENA Connection Weights* do not explicitly normalize for the base rates of individual codes. As a result, ENA may prioritize patterns involving more prevalent codes, while potentially obscuring stronger and more informative associations among less frequent codes.

ARM and ENA each have many variants, including widely used variants that extend their base approach to explicitly account for the temporal order of events or codes. For ARM, the most popular extension is Sequential Pattern Mining (SPM; [2]) and for ENA, it is Ordered Network Analysis (ONA; [34]). While these variants enable the analysis of sequential patterns rather than only unordered co-occurrences, they largely inherit the conceptual strengths and

limitations of their underlying methods, including how associations are quantified, normalized, and ultimately interpreted.

The existence of multiple analytic approaches to analyzing the relationship between discrete variable values raises an important question for educational researchers: What method do I use? Each of these algorithms and metrics within it seeks to quantify the strength/importance of connections in data, but it is not clear which is most likely to yield meaningful and useful conclusions about learning processes.

Prior work in EDM has attempted to address this question by comparing different ARM metrics against patterns deemed relevant by human experts, in order to assess which metrics reveal patterns that are most meaningful in educational contexts. For example, Merceron and Yacef [19] examined four ARM metrics in a small-scale case study of student assessment data, arguing in favor of metrics that are intuitive for educators and robust to limited data. Their results highlight base-rate-adjusted metrics (i.e., *Cosine* and *Lift*) as especially suitable for educational applications.

Building on this work, Bazaldua et al. [5] asked human experts to evaluate the importance of a range of 21 ARM metrics. Specifically, they asked the human raters which patterns were *theoretically aligned* and *interesting* (to the human raters). They found that *Phi coefficient*, *Conviction*, and *Jaccard* were among the strongest predictors of human judgments. However, *Jaccard*, *Phi*, *Conviction*, and 16 other metrics were actually ***negatively*** associated with human ratings of interestingness. This finding demonstrates the complexity of identifying patterns that researchers genuinely find interesting, rather than patterns that merely reflect expected relationships, yielding accurate but ultimately trivial conclusions.

These studies investigated expert judgments about the importance and interestingness of the identified patterns but did not evaluate how useful the patterns were in terms of research findings. An alternative and complementary approach to those used in prior studies is therefore to assess discovered patterns in terms of whether they are related to external measures of key educational constructs, such as situational interest, self-efficacy, learning gains, and other motivational or cognitive variables. We can then ask human experts to evaluate not only the patterns themselves but also the identified associations. Accordingly, this study extends prior work by addressing the following research questions: **(RQ1)** which pattern mining methods, and strategies for aggregating connections or sequences, are most effective at identifying patterns among coded events that are associated with external measures of learning and motivation, and **(RQ2)** which of the metrics produces associations to external measures of learning and motivation that are meaningful to domain experts? This approach enables an explicit comparison of pattern mining methods not only in terms of what domain experts find interesting, but also what they find important, namely, their consequential validity.

2. RELATED WORK

2.1 Association Rule Mining

Association Rule Mining (ARM) is a data mining technique used to identify associations among items, events, or codes in large datasets [1]. ARM seeks to discover rules expressed as implication statements of the form X→Y, where the antecedent (X) consists of one or more conditions whose occurrence is associated with an increased likelihood of the consequent (Y). For example, a rule identified through ARM might indicate that when a student visits a point of interest and uses a scientific tool to measure a physical variable (antecedent), the student is likely to make a scientific observation (consequent). Importantly, the antecedent-consequent relationship in ARM does not imply temporal order. In this example, the scientific observation may have occurred before the tool use or the visit to the point of interest. Rather than modeling a sequence of events, ARM captures conditional relationships among sets of events or constructs.

Sequential Pattern Mining (SPM) extends ARM by explicitly incorporating temporal order into the discovery of patterns [2]. Rather than identifying unordered co-occurrences, SPM focuses on discovering frequent sequences of events in which antecedent events must temporally precede consequent events within a specified temporal window, transaction, or conversation. This makes SPM particularly suitable for modeling processes that unfold over time, such as learning trajectories or sequences of student actions. For example, SPM could be used to evaluate whether a visit to a point of interest and scientific tool use (antecedent) temporally precedes the student's scientific observation (consequent).

In the EDM literature, both ARM and SPM have been used in a range of projects. ARM has been used to identify patterns of student actions within learning management systems, such as combinations of content access and assessment activities, which were then examined to better understand differences between high- and low-performing students [24]. Similarly, Hwang et al. [11] applied ARM to show that students who struggled with foundational concepts were more likely to fail subsequent, dependent items. SPM has been used to capture the temporal structure of learning and collaboration. For example, Perera et al. [23] analyzed trace data from student teams working in a professional software development environment and identified distinct temporal patterns of tool use and interaction associated with effective coordination, leadership, and task management. Martínez et al. [17] applied SPM to interaction traces from student collaborations using a shared interactive tabletop. Their analysis revealed systematic differences associated with group achievement: successful groups engaged in parallel, discussion-rich interactions and actively externalized their thinking, whereas lower-achieving groups tended to interact sequentially with the same resources.

Kinnebrew et al. [12] extended SPM by proposing Differential Sequence Mining, an exploratory pattern mining approach designed to identify activity sequences that occur differentially across groups or phases of learning. Applied to interaction data from an intelligent tutoring system, this method revealed that high-performing students more frequently engaged in monitoring behaviors, such as assessing their progress and reflecting on recent actions. Overall, this body of work demonstrates the value of ARM and SPM in revealing interpretable temporal patterns in learning data that support a deeper understanding of diverse learning processes.

2.1.1 Interestingness Metrics

In ARM and SPM, patterns can be discovered using several methods [21]. The choice of method depends on the type of patterns researchers aim to highlight (e.g., ordered sequences of events or co-occurrences within a specific time window) [21], as well as the computational resources required for different data sizes and the size of the candidate itemset space (i.e., the number of possible combinations of events or codes that can be formed from the available set of items) [16].

Across these methods, the discovery process typically involves identifying frequent itemsets—sets of events or codes that co-occur within the units of analysis (e.g., student study sessions, problem

attempts, or conversations)—based on a minimum *Support* threshold. *Support* measures how frequently a rule or pattern occurs in the dataset and is defined as the proportion of transactions or instances in which both the antecedent (X) and the consequent (Y) appear together (P(XY)). As such, *Support* captures prevalent or common patterns, favoring rules that represent behaviors or events that occur frequently.

After identifying itemsets with high *Support* (i.e., frequent co-occurrence), implication rules of the form X→Y are generated and evaluated using a variety of metrics that quantify different aspects of the relationship between the antecedent (X) and the consequent (Y). The most commonly used metric is *Confidence*, which estimates the conditional probability of observing the consequent given the antecedent, P(Y|X). As such, it emphasizes conditional reliability, or how consistently the occurrence of X is associated with the occurrence of Y. *Confidence*-based rules capture asymmetric relationships and are particularly useful for identifying cases in which one behavior reliably accompanies another, even when the reverse association does not hold.

Though widely used, *Support* and *Confidence* also have well-documented limitations [19]. For example, while high *Support* characterizes dominant or typical behaviors, it may overlook less frequent but potentially meaningful patterns. Similarly, *Confidence* does not account for the overall frequency of the consequent and may therefore overestimate the strength of associations involving high-frequency events or codes.

To address these limitations, a range of so-called *interestingness metrics*, explicitly normalize association rules by the marginal frequencies (base rates) of the antecedent and/or consequent [33]. Metrics such as *Cosine* capture the similarity between the occurrence vectors of X and Y by normalizing their joint frequency by the geometric mean of their individual frequencies, thereby emphasizing the strength of association while reducing the influence of highly frequent events. Similarly, *Lift* compares the observed co-occurrence of X and Y with what would be expected if they were statistically independent, highlighting associations that are stronger than chance. *Added Value* also measures the extent to which the occurrence of X increases the likelihood of Y beyond its baseline probability. More broadly, Tan et al. [33] catalogued more than twenty such metrics, all designed to surface non-trivial or surprising patterns that may be less frequent but more informative about underlying learning processes.

Among these metrics, Merceron and Yacef [19] recommend *Lift*, *Added Value*, and *Cosine* as especially suitable metrics for educational data, after first filtering out rules with low *Support* and *Confidence*. They argue that these metrics are intuitive for non-data-mining experts (e.g., teachers or school administrators) while remaining informative for identifying non-trivial associations. At the same time, they emphasize that no single metric is sufficient for identifying pedagogically meaningful rules. Different metrics surface different types of patterns—such as frequent behaviors, reliable conditional relationships, or associations that stand out relative to overall frequency—and their usefulness depends both on the research goal and on the interpretability of the resulting rules for educators and researchers. Accordingly, they emphasize the need to compare rules across multiple metrics to obtain a more nuanced view of learner behavior and to support more robust and meaningful conclusions.

Motivated by this need to identify which of the many available *interestingness metrics* are most informative for educational stakeholders, Bazaldua et al. [5] conducted a systematic comparison of a wide range of metrics using interaction data focused on affective states and learner behaviors in an educational platform, together with ratings provided by three domain experts familiar with the learning context. In their study, a large set of association rules was first generated from student interaction logs and filtered using minimum *Support* and *Confidence* thresholds. The experts then rated the interestingness of each rule using a Likert scale, providing a human benchmark against which rankings of rules induced by different *interestingness metrics* could be compared. The authors evaluated not only *Cosine*, *Lift*, and *Added Value*, but also several additional metrics—including the *Phi coefficient*, *Conviction*, and *Jaccard*—drawn from the set of metrics compiled by Tan et al. [33]. Their results showed that multiple metrics were predictive of expert judgments, with metrics such as the *Phi coefficient*, *Conviction*, and *Jaccard* exhibiting stronger alignment with human ratings. However, only *Lift* showed a positive association with expert judgments across the 21 evaluated metrics, while most showed significant negative associations. This finding highlights that what human analysts consider interesting may differ substantially from what *interestingness metrics* prioritize.

2.2 Epistemic Network Analysis

Epistemic Network Analysis (ENA; [27]) is a technique used in the quantitative ethnography (QE) community to model the structure of relationships among a set of theoretically meaningful constructs or codes. ENA has been applied across a wide range of contexts, including analyses of learning processes in digital learning environments [28], task performance [25], gaze patterns [3], team communication [31], social media interactions [9], and video game player behavior [39].

ENA operationalizes relationships among constructs by quantifying their co-occurrence within segments of coded data, typically organized into conversations or horizons (analogous to transactions in ARM and SPM) and aggregated across learners, groups, or tasks. Connections between constructs are accumulated using a moving window that links codes appearing in the same or recent prior lines of discourse, thereby capturing local temporal proximity without imposing strict sequential constraints [7, 27]. These co-occurrence counts are aggregated for each unit of analysis (e.g., learners or groups), then normalized using cosine or spherical normalization (distinct from the *Cosine interestingness metric* used in ARM) to account for differences in the amount of coded data across units. Finally, dimensionality reduction techniques are applied to project the resulting normalized vectors into a two-dimensional space, facilitating statistical and visual comparison across units and groups.

In ENA visualizations, each unit of analysis is represented both as a weighted network graph and as a point in a two-dimensional space corresponding to the network's centroid (or mean). In these network representations, nodes correspond to events or constructs used to code the data, and edges represent the relative strength of co-occurrence between pairs of constructs. Spatial proximity between constructs should not be interpreted as a direct measure of association strength. In ENA, node positions are derived from the overall structure of variance in the network space, so constructs that appear closer together may reflect similar contributions to the underlying dimensions rather than consistently stronger co-occurrence. On the other hand, the relative positions of constructs and unit centroids are interpretable, as they reflect which constructs and connections most characterize a given unit's network. For example, if a student *i* is positioned closer to construct A than to construct C, it indicates that the interaction patterns associated with

student *i* more strongly involve construct A. In this way, differences in the positions of units of analysis can also be interpreted as differences in their underlying connection patterns, enabling researchers to compare individual networks, group means, and network differences within a shared analytical space (acknowledging the limitations inherent to any dimensionality reduction).

ENA's primary strength lies in its ability to represent and compare complex patterns of pairwise associations among multiple constructs in rich, temporally indexed data, while maintaining a strong emphasis on interpretability through visual representations. However, ENA also embodies specific analytic assumptions that shape the types of patterns it can reveal. Standard ENA models capture only pairwise (dyadic) associations and treat connections as symmetric, focusing on co-occurrence rather than conditional dependence. As a result, ENA connection weights tend to be highly correlated with the *Support* metric commonly used in frequency-based pattern mining approaches [38]. Consequently, *ENA connection weights* are subject to similar limitations as *Support*, which does not take into account the base rates of individual codes, and does not capture the nuances emphasized by conditional metrics (e.g., *Confidence*) or base-rate-adjusted metrics such as *Cosine*, *Lift*, *Added Value*, and related *interestingness metrics*.

Chronological ordering has been incorporated into the ENA framework through Ordered Network Analysis (ONA; [34]). Like SPM, this method constrains connections based on temporal precedence and thus distinguishes temporally between X→Y and Y→X. However, unlike *Confidence* and many *interestingness metrics*, ONA does not model these relationships in terms of conditional probability or statistical independence. Additionally, like ENA, ONA relies on co-occurrences as the primary mechanism for highlighting important patterns, and is thus also susceptible to identifying patterns that are driven primarily by high base rates rather than by genuine implication-based relationships between codes.

2.3 Contributions of this Study

Although ARM and SPM offer a wide range of *interestingness metrics* and support the identification of patterns involving three or more codes or events, it remains unclear whether all of these metrics and higher-order patterns (i.e., patterns involving three or more codes or events) meaningfully enhance interpretation in educational research. Methods such as ENA and ONA were developed to provide qualitative researchers with a quantitative framework for identifying meaningful patterns that can then be interpreted through domain expertise to "close the interpretative loop" and support robust, data-driven conclusions about educational phenomena [27]. Merceron and Yacef [19] argue that pattern mining should rely on metrics beyond *Support*, rather than primarily on co-occurrence-based measures such as those used in ENA. However, Bazaldua et al. [5] show that these alternative metrics do not necessarily align more closely with the patterns human researchers find interesting. This discrepancy reflects the challenge of defining what makes a pattern "interesting," a term generally used without reflection in early mathematical work on *interestingness metrics*. Instead of relying on the term alone, we evaluate metrics based on whether the patterns they produce connect to validated external measures of important motivational and cognitive constructs. We then build on Bazaldua et al. [5] and ask domain experts to assess whether these associations (not only the patterns themselves) are meaningful and interesting. By doing so, we can better assess which metrics are most informative for educational research and for supporting the interpretative process.

3. METHODS

3.1 Educational Context

The dataset for this study was collected from eight 5-day summer camps conducted in 2024 and 2025 as part of the *What if Hypothetical Implementations in Minecraft* (WHIMC) project [13], and has been previously published in [40]. WHIMC uses *Minecraft: Java Edition* to engage learners in exploring hypothetical astronomy scenarios through "What if" questions (e.g., "What if Earth had no moon?" or "What if Earth orbited a colder sun?"). During the first three days of each camp, students, guided by pedagogical agents (NPCs) and human facilitators, evaluated the habitability of a range of hypothetical worlds and real exoplanets modeled in Minecraft. During the final two days, students explored a Mars map generated from real terrain data and designed shelters capable of sustaining human life.

During each camp, students completed twelve motivational and learning assessments (see Table 1). On day 1, they completed Boeder et al.'s [6] interest development scale and Gadbury's [10] adaptation of LoPresto and Murrell's [15] astronomy knowledge test. On day 3, students completed Gadbury's [10] astronomy and Minecraft interest survey. On day 4, they completed Linnenbrink-Garcia et al.'s [14] situational interest scale and Britner and Pajares' [8] self-efficacy scale, and they also repeated the day 1 instruments. Three surveys (situational interest, astronomy interest, and *Minecraft* interest) were not administered during the first camp; these instruments were added beginning with the second camp.

Table 1. Interest and knowledge assessments.

Instrument	Day	Camps	N
Boeder et al.'s Interest Development	1	8	104
Gadbury et al.'s Knowledge Assessment	1	4	52
NSS Astronomy Knowledge Assessment 1	1	4	46
Camp-specific Knowledge Assessment	2	3	31
Gadbury et al.'s Astronomy Interest	3	7	82
Gadbury et al.'s Minecraft Interest	3	7	82
Boeder et al.'s Interest Development	4	7	88
Linnenbrink-Garcia et al.'s Situational Interest	4	7	88
Britner & Pajares' Self-efficacy	4	8	101
Gadbury et al.'s Knowledge Assessment	4	4	47
Camp-specific Knowledge Assessment	4	4	44
NSS Astronomy Knowledge Assessment 2	4	4	43

The knowledge assessment was revised between the 2024 and 2025 camps to better align with core astronomy concepts. A second instrument, based on the National Science Standards (NSS; [26]), was introduced. This instrument assessed concepts addressed during camp activities (e.g., eclipses, tides, seasons, rotation speed, and orbital periods) on day 1, as well as students' ability to transfer those concepts to constructs not covered during the camp on day 5. A separate knowledge assessment was also administered at the beginning of days 2 and 4 to evaluate concepts targeted in the exploration worlds; it was not administered on day 1, which was primarily devoted to orientation and familiarization with facilitators and the game environment rather than learning-focused activities. Normalized learning gains were calculated for each knowledge assessment as the ratio of a student's observed improvement (or decline) to the maximum possible change [18].

A total of 118 students from urban and rural areas across four states participated in the summer camps. The sample included 72 male, 40 female, and 3 non-binary students, as well as 3 students who

preferred not to disclose their gender. Participants self-identified as 44 White, 49 African American, 7 Hispanic/Latinx, 2 Native American, 10 Other, and 6 who preferred not to disclose their race/ethnicity. Participation was voluntary, and written assent and parental consent were obtained for all students. 13 students were excluded from the analyses because they did not complete any surveys or lacked recorded activity interaction logs on multiple days. No significant demographic differences were observed between the excluded and included participants.

3.2 Coding of Gameplay Log Data

Our current study uses previously coded data [40] from the first three days of the summer camp, during which students explored different "What if" worlds to identify physical variables, observe environmental changes, and assess potential human habitability. These days were selected because the worlds exhibit similar, scientifically-grounded behaviors, allowing a single codebook to be applied consistently across all three. The structured nature of these activities also supports greater consistency across camps held in different locations.

Students were free to explore the worlds at their own pace (moving quickly or slowly, independently or collaboratively) while observing areas of interest, measuring physical variables, and sharing observations with other players through written messages within the virtual environment. The interaction logs recorded each student's X, Y, and Z coordinates every three seconds, along with the in-game commands used to carry out these actions. The codes (i.e., behavioral constructs) reported in [40] were derived from these log data and corresponded directly to seven observable student actions during the exploration period (see Table 2).

Table 2. Codebook proposed by [40].

Code	Definitions
Non-stopping/ Racing	The student has stopped for less than 6 seconds during the last minute. A stop corresponds to moving less than three blocks during a period of three seconds.
Social Movement	The student was less than 20 blocks from another player during the entire last minute.
Individual Movement	The student was more than 35 blocks away from any other player during the entire last minute.
Point of Interest	The student is inside a point of interest for 10 seconds or more. Every 10 seconds within the Point of Interest trigger this code again.
Talk to NPCs	The student is within 4 blocks or less of an NPC for 10 seconds or more. Every 10 seconds close to the NPC trigger this code again.
Science Tool	The student uses a scientific tool to measure a physical variable.
Scientific Observation	In-game observations in which students describe the virtual world, ask a science-related question, or attempt to comprehend scientific concepts (e.g., "Can humans survive without the moon?").

Whenever a student action met the definition of a code, a new utterance was created and coded under the corresponding category, with each utterance assigned to a single category. When actions could co-occur (e.g., using a tool while visiting a point of interest), two separate utterances were generated.

The threshold for the Non-Stopping code was established by examining the distributions of students' movement speeds and stops, taking into account the three-second sampling interval of the location data. We defined the Non-Stopping code by the number of stops instead of rapid movement indicators because of the nature of the WHIMC learning environment, where students are expected to conduct activities that require brief pauses in movement (i.e., measure physical variables or make observations).

The threshold for the Individual Movement code was based on the maximum in-game field of view (35 blocks). For the Social Movement code, we used a distance of approximately half that value (20 blocks) to capture instances in which students were in close proximity to others, rather than merely observing them from a distance.

Points of Interest refer to specific in-game locations that students are expected to visit. A duration threshold of 10 seconds was selected for this code because 95% of visits to these areas lasted at least that long. Similarly, interactions with NPCs occur through text boxes that automatically appear when students are within 4 blocks of an NPC; this distance was therefore used as the threshold for defining the Talk to NPC code. The 10-second duration threshold for this code follows the same rationale used for the Points of Interest code.

Finally, the Scientific Observations code captures in-game written observations in which students describe aspects of the virtual world, pose science-related questions, or attempt to reason about scientific concepts. The dataset was manually coded by two human coders [40], who initially achieved strong interrater reliability (Cohen's $\kappa > 0.75$) for each of the three subtypes of scientific observations (Description, Questioning, and Reasoning). For the purposes of [40], these subtypes were subsequently aggregated into a single code for analysis, a methodological decision we follow here.

3.3 Statistical Analysis Compared

In this study, we compare a range of metrics to determine how the choice between ARM and ENA-based methods might affect our results. We do so by applying metrics derived from these methods to the coded behavioral data and then comparing those results to the external knowledge and motivational variables. Specifically, for each identified rule or connection, we computed Spearman's rank correlation coefficients (ρ) between the corresponding ENA connection weight or ARM metric and each external education-related measure. This analysis aimed to identify which pattern mining metrics most consistently highlighted patterns associated with constructs assessed using validated knowledge and motivation instruments.

Based on previous research [5, 19], we selected the following ARM and SPM metrics for analysis: *Support*, *Confidence*, *Cosine*, *Lift*, *Added Value*, *Jaccard*, *Conviction*, and the *Phi coefficient*. These metrics were analyzed alongside the *Connection Weights* generated by ENA and ONA.

For ENA and ONA, connections are computed using a moving-window approach with a stanza size of four instances, which is the most commonly used window size and aggregation method in the QE literature [30]. To ensure methodological consistency and facilitate comparability across approaches, the same window size is used to define transactions for ARM and SPM, following prior work that compared these methods [38].

3.3.1 Understanding each Pattern Mining Metric

To examine the similarity of results from different pattern mining methods and metrics, we first assess the associations among all metrics across both ARM- and ENA-based approaches over the full

set of identified patterns. To this end, we employ a mixed-effects linear model comparing metric values across patterns and students. This approach was chosen over simple correlation analyses to account for the non-independence introduced by multiple patterns identified for the same student. In addition, all metrics were rank-transformed prior to analysis to enable the assessment of non-linear associations between them.

Six metrics examined in this study are inherently symmetric. Specifically, *ARM Support*, *Jaccard*, *Cosine*, *Lift*, *Phi*, and *ENA Connection Weights* assign one rule to both X→Y and Y→X. In contrast, three asymmetric metrics (i.e., *Confidence*, *Added Value*, and *Conviction*) can yield different values depending on the rule direction. All SPM and ONA metrics are also inherently asymmetric because they depend on temporal order. To facilitate comparisons between symmetric and asymmetric metrics, we split the symmetric rules into two rules (X→Y and Y→X) with identical numerical values.

To further understand the types of rules emphasized by each pattern mining method and metric, we conducted a complementary analysis. For each method, we identified the ten highest-ranked rules and computed five descriptive statistics for each rule. These statistics included the base rate (*Support*) of the antecedent, consequent, and their co-occurrence; the conditional probability of the consequent given the antecedent (equivalent to *Confidence*); and the ratio of the co-occurrence base rate to the individual base rates (equivalent to *Lift*). Because rules involving a single item naturally exhibit higher overall support and are not represented in ENA, this analysis was restricted to rules involving two distinct items or codes (three or more naturally exhibit lower support and are also not represented in ENA).

3.3.2 Connections with External Measures

For each metric and method, we counted the number of statistically significant correlations between pattern-level metrics (e.g., *Support*, *Confidence*, or *ENA Connection Weights*) and external knowledge or motivational measures. Importantly, the purpose of this analysis was not to interpret individual significant correlations but to compare how frequently different metrics and methods identified associations with external constructs. Accordingly, no correction for multiple comparisons was applied, because the count of significant associations served as a comparative indicator rather than as evidence supporting specific inferential claims.

ARM, SPM, ENA, and ONA differ in the number and types of patterns they can identify (e.g., ENA is limited to dyadic relations), which may inflate the number of significant associations with external measures for methods that generate larger pattern sets, such as ARM and SPM. However, after applying an initial filtering step that removed patterns with *Support* or *Confidence* below 0.05, a standard procedure recommended by Merceron and Yacef [19], all patterns involving rules with more than two codes were eliminated, indicating that such higher-order patterns were not common in this dataset. This result suggests that the observed differences in the number of significant associations across methods are not driven by ARM-based approaches identifying more complex patterns but rather reflect substantive differences in how each metric and method quantifies dyadic patterns.

The only adjustment made to the count of significant associations concerned the symmetric nature of certain metrics. As noted earlier, *ARM Support*, *Jaccard*, *Cosine*, *Lift*, *Phi*, and *ENA Connection Weights* assign identical values to the rules X→Y and Y→X. Consequently, these methods would be expected to yield approximately half as many significant associations as methods that distinguish between X→Y and Y→X (though not exactly half, due to significant correlations involving single-code patterns). For this reason, we treated X→Y and Y→X as separate rules when computing correlations, even for symmetric metrics where their numerical values were identical.

Additionally, patterns involving single events (i.e., marginal probabilities of individual codes) were included. For this type of pattern, ONA provides a comparable representation through self-transitions (X→X). In contrast, ENA and some ARM metrics, such as *Conviction* or *Phi*, do not offer directly analogous metrics for single-code rules, which may slightly reduce the number of significant associations identified by these methods. However, because this limitation is specific to those methods and metrics, and because single-event associations have substantial interpretive value for understanding direct relationships between individual codes and outcomes, these rules were retained.

3.4 Human Ratings of Pattern Importance

A large proportion of our analysis is based on metrics that do not involve human judgement, but instead describe other aspects of the patterns' frequency, reliability, and non-randomness. These metrics, like the other measures in this study, are important for quantifiably describing patterns, but do not necessarily indicate whether those associations are meaningful to expert researchers. In both the EDM and QE communities, the goal is not merely to identify patterns, but to determine which observed patterns support meaningful conclusions [27]. In other words, we are interested in which research methods (or metrics) are most likely to lead to consequential validity [37].

Building on this perspective, we examine which of the statistically significant correlations highlighted by each technique are theoretically meaningful and relevant to researchers. As in previous research that has sought to distinguish ARM metrics of interestingness from human ratings of interestingness [5], we used a five-point Likert scale to evaluate both the *theoretical alignment* and the *perceived interestingness* of each identified correlation. Five educational researchers (all coauthors) independently rated the correlations while blinded to the pattern mining technique and metric that produced each result. All raters evaluated the same set of 203 statistically significant correlations, defined as those identified by at least one pattern mining method or metric. After completing the ratings, raters were also asked to describe their rationale for judging correlations as interesting.

The five ratings for each dimension were aggregated using a 40% trimmed mean, in which the highest and lowest ratings were discarded, and the remaining three were averaged. Trimmed means are a standard robust aggregation procedure that reduces the influence of outliers [36]. Finally, correlations falling in the top 10% for both interestingness and theoretical alignment were examined across pattern mining methods and metrics to determine which techniques identified these correlations and whether the methods agreed on the direction of the associations.

4. RESULTS

4.1 Method-Metric Similarity

We first consider how the observed associations among the different ARM- and ENA-based metrics compare to one another. Overall, the results show a general pattern of positive association across most metrics (Figure 1). However, important differences emerge between patterns that highlight simple frequency and those that account for base rate differences in the components of a pattern.

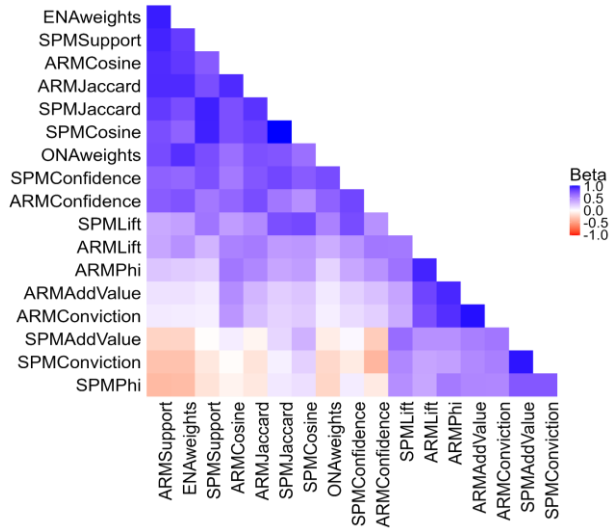

Figure 1. Associations between multiple pattern mining methods and metrics.

In particular, *Support*, *Confidence*, *Cosine*, and *Jaccard* (for both ARM and SPM), as well as ENA and ONA connection weights, are strongly associated with one another, indicating a tendency to highlight similar patterns. In contrast, *Added Value*, *Conviction*, and *Phi* exhibit negative associations with this group of metrics when computed in the context of SPM, and exhibit near-zero associations when computed for ARM. *Lift* occupies an intermediate position, showing moderate associations with *Phi* as well as with *Cosine*, but not reaching the same level of strong association observed within either of the two main clusters of measures. These results show that *Added Value*, *Conviction*, and *Phi* emphasize patterns that differ systematically from those highlighted by the remaining measures.

We further demonstrate the distinctions in these metrics by examining the details of the baseline probabilities associated with each metric. Table 3 reports the average base rates of the antecedent (P(X)), the consequent (P(Y)), their co-occurrence (P(XY)), the conditional probability of the consequent given the antecedent (P(Y|X)), and the ratio (*Lift*) of the joint probability (P(XY)) to the product of the individual probabilities (P(X)P(Y)) for the top 10 rules identified by each method and metric (i.e., the highest-scoring rules per metric). Multiple threshold values were tested (e.g., top 5 rules to top 20), yielding consistent results. Across the combined top-10 lists from the 18 methods and metrics considered, 31 unique patterns were identified, with most appearing among the top-ranked rules for at least 12 methods. Antecedent and consequent base rates ranged from 0.22 to 0.44, co-occurrence probabilities ranged from 0.08 to 0.16, and *Lift* values ranged from 0.96 to 1.28, indicating that different methods emphasize patterns with distinct statistical characteristics.

As expected based on the definitions of these metrics (see [33]), methods that primarily emphasize high-frequency constructs, such as *Support*, *ENA*, and *ONA Connection Weights*, tend to highlight rules in which both the antecedent and the consequent had relatively high base rates. In contrast, metrics such as *Lift*, *Phi*, *Added Value*, and *Conviction* did not emphasize rules composed of high base rate antecedents and consequents. Instead, these metrics tended to highlight rules in which the antecedent and consequent co-occurred in ways that were not primarily driven by their individual frequencies.

Table 3. Base rates and co-occurrence statistics for top-10 rules identified by each method, sorted on joint probability.

Method	Metric	P(X)	P(Y)	P(XY)	P(Y|X)	P(XY) / (P(X)P(Y))
ARM	Support	0.390	0.390	0.157	0.411	1.034
ENA	Weights	0.387	0.387	0.157	0.400	1.047
ONA	Weights	0.407	0.385	0.155	0.381	0.988
SPM	Support	0.410	0.360	0.153	0.373	1.032
ARM	Cosine	0.360	0.360	0.152	0.423	1.167
ARM	Jaccard	0.360	0.360	0.152	0.423	1.167
SPM	Jaccard	0.387	0.354	0.149	0.397	1.085
SPM	Cosine	0.391	0.348	0.149	0.385	1.094
SPM	Confidence	0.343	0.371	0.144	0.421	1.134
ARM	Confidence	0.302	0.439	0.135	0.440	1.016
SPM	Lift	0.337	0.325	0.132	0.396	1.202
ARM	Add. Value	0.314	0.314	0.126	0.393	1.277
ARM	Conviction	0.314	0.314	0.126	0.393	1.277
ARM	Lift	0.314	0.314	0.126	0.393	1.277
ARM	Phi	0.314	0.314	0.126	0.393	1.277
SPM	Phi	0.272	0.305	0.092	0.335	1.102
SPM	Conviction	0.367	0.221	0.081	0.221	1.003
SPM	Add. Value	0.376	0.223	0.081	0.220	0.964

Consistent with its definition, *Confidence* emphasizes rules in which the consequent (Y), but not necessarily the antecedent (X), had a high base rate, reflecting its focus on maximizing the probability of the consequent given the antecedent. Notably, *Cosine*, although conceptually related to *Lift*, appeared to reflect a trade-off among these tendencies, highlighting patterns that fell between these extremes in terms of base rates and conditional relationships relative to the other metrics and methods considered.

4.2 Correlations with External Instruments

One measure of consequential validity is the degree to which the patterns identified in these metrics are associated with meaningful outcome measures. As such, Table 4 summarizes the total number of statistically significant correlations identified between each pattern mining metric and the external knowledge and motivational instruments. Correlations involving knowledge assessments administered at the beginning of the camp were grouped under the Pre-test category. Similarly, correlations involving knowledge assessments collected at the end of the camp were grouped under Post-test, and correlations related to learning gains, computed from multiple knowledge assessments, were grouped under the Learning category.

Across all motivational and knowledge measures, *Support* emerged as the pattern mining metric that identified the largest number of significant associations with the external instruments. Specifically, ARM *Support* and SPM *Support* yielded 143 and 142 significant correlations, respectively. These were followed by *Confidence*, which produced 140 significant correlations for ARM and 121 for SPM. Similarly, *ONA* and *ENA Connection Weights* showed comparatively high numbers of significant associations (127 and 120, respectively), indicating that metrics that do not adjust for code base rates were consistently related to external measures of knowledge and motivation. Notably, across all instruments, no metric outside this set of six produced the highest number of significant correlations, underscoring the consistency of these trends across external measures.

Table 4. Significant correlations identified with each pattern mining metric across all the knowledge and motivational measures.

Method	Metric	Pre Test	Post Test	Learning	Initial Sit. Int.	Final Sit. Int	Self-Efficacy	Astronomy Int.	Minecraft Int.	Total
ARM	Support	20	**44**	37	13	11	**6**	9	**3**	**143**
SPM	Support	20	43	38	13	**12**	4	**10**	2	142
ARM	Confidence	17	**44**	**40**	**16**	10	5	7	1	140
ONA	Weights	17	38	36	13	10	2	9	2	127
SPM	Confidence	15	38	31	14	10	5	5	**3**	121
ENA	Weights	**22**	40	32	8	8	2	6	2	120
SPM	Conviction	14	36	32	14	9	4	6	2	117
SPM	Added Value	12	36	28	11	9	4	5	**3**	108
ARM	Jaccard	18	31	29	7	10	3	5	**3**	106
ARM	Cosine	17	26	32	4	9	3	8	**3**	102
SPM	Jaccard	18	32	30	6	8	2	4	2	102
SPM	Cosine	12	24	29	5	5	2	4	**3**	84
SPM	Phi	9	35	30	1	1	1	1	0	78
ARM	Added Value	11	22	18	1	2	2	3	0	59
ARM	Lift	6	26	18	0	0	4	0	0	54
ARM	Conviction	9	20	19	0	0	1	0	0	49
SPM	Lift	6	18	14	0	3	5	1	1	48
ARM	Phi	10	14	14	0	0	0	0	0	38

In contrast, metrics designed to adjust for base rates or to emphasize non-trivial associations were less consistently associated with the external instruments. Specifically, the *Phi coefficient* (38 significant correlations for ARM and 78 for SPM), *Lift* (54 for ARM and 48 for SPM), and the ARM versions of *Conviction* and *Added Value* (49 and 59 significant correlations, respectively) exhibited substantially fewer associations with knowledge and motivational measures, a pattern that was consistent across all instruments considered. These findings suggest that patterns involving highly frequent codes and their co-occurrences may be more strongly associated with differences in student interest, self-efficacy, prior knowledge, or learning gains, even when such patterns are partly driven by high base rates rather than strong conditional dependence. In other words, adjusting for base rates does not, in this case, appear to produce patterns that are more closely aligned with external educational measures.

It is important to note that symmetric metrics—such as *Support* (for ARM) and *ENA Connection Weights*—do not distinguish between X→Y and Y→X, unlike asymmetric metrics, including SPM-based metrics, *ONA Connection Weights*, and ARM metrics such as *Confidence*, *Added Value*, and *Conviction*. As a result, symmetric metrics inherently represent only half of the distinct directional patterns that can be identified by asymmetric rules. As noted earlier, symmetric rules were therefore counted twice when tallying significant correlations to ensure comparability with asymmetric metrics.

Notably, after applying this adjustment, ARM *Support* and *ENA Connection Weights* yielded totals of significant associations that were nearly identical (and even greater for the case of *Support*) to those obtained using asymmetric metrics such as SPM-based metrics, *Confidence*, and *ONA Connection Weights*. This pattern suggests that incorporating temporal ordering (as in SPM and ONA), or conditional directionality (as captured by *Confidence*), does not necessarily provide substantial additional information beyond what is already captured by co-occurrence alone, at least with respect to associations with external measures. In the context of this data set, the primary relationships between codes and educational constructs appear to be driven more by co-occurrence than by the direction or temporal ordering of events.

4.3 Human Ratings Results

Finally, we examine which patterns were rated as important by expert human judges. Table 5 presents the number of significant correlations identified by each method among the top 10% of correlations rated as most *theoretically aligned* and *interesting* by human raters. Due to tied ratings, this resulted in 38 correlations rated as most *theoretically aligned* (average score ≥ 4.67) and 22 correlations rated as most *interesting* (average score ≥ 4.00). The table also shows how often each metric identified a significant correlation in the direction that raters judged to be *theoretically aligned* or *interesting*. Notably, ratings of *theoretical alignment* differed markedly from ratings of *perceived interestingness* (Spearman's $\rho = -0.781$, $p < .001$) and there was no overlap between the top 10% of correlations identified for the two ratings.

Table 5. Significant associations identified by each metric among highly rated theoretically aligned and interesting patterns. Symmetric rules were counted twice to ensure comparability with asymmetric metrics.

		Theoretical Alignment		*Interestingness*	
Method	**Metric**	**Significant**	**Direction**	**Significant**	**Direction**
ARM	Support	28	28	13	6
ONA	Weights	26	26	10	5
ARM	Confidence	25	25	12	8
SPM	Confidence	25	25	13	9
SPM	Support	25	25	13	5
ARM	Cosine	23	23	8	6
ARM	Jaccard	22	22	9	5
SPM	Cosine	22	22	11	6
SPM	Jaccard	21	21	9	5
ENA	Weights	18	18	8	2
ARM	Lift	9	5	13	10
ARM	Add. Value	8	4	11	10
SPM	Add. Value	18	4	13	9
SPM	Conviction	18	4	15	10
SPM	Lift	6	4	9	7
ARM	Conviction	3	1	5	4
ARM	Phi	6	1	7	7
SPM	Phi	11	1	10	8

Support identified the largest number of correlations with high *theoretical alignment* (N = 28 for ARM and N = 25 for SPM), followed by *ONA Connection Weights* (N = 26), *Confidence* (N = 25 for both ARM and SPM), *Cosine* (N = 23 for ARM and N = 22 for SPM), *Jaccard* (N = 22 for ARM and N = 21 for SPM), and *ENA connection weights* (N = 18). Notably, all correlations highlighted by these methods exhibited a direction that was consistent with both theoretical expectations and raters' judgments. These results indicate that this cluster of metrics, which also showed stronger mutual associations and similar pattern emphasis (see Section 4.1), tends to identify patterns that align closely with theory and human expectations.

In contrast, the second cluster of metrics (*Added Value*, *Conviction*, the *Phi coefficient*, and, to a lesser degree, *Lift*) tend not to highlight rules that were *theoretically aligned*. For example, although *SPM Added Value* and *Conviction* each identified 18 significant correlations that raters judged as *theoretically aligned*, only four of those correlations exhibited the expected direction.

This mismatch between the theoretically expected direction and the actual direction of the associations surfaced by this second cluster of pattern mining metrics helps explain why those associations ranked higher when they were evaluated primarily in terms of *perceived interestingness* rather than *theoretical alignment*. *Added Value* (N = 10 for ARM and N = 9 for SPM), *Conviction* (N = 10 for SPM and N = 4 for ARM), and *Lift* (N = 10 for ARM and N = 7 for SPM) were the metrics that identified the largest number of correlations whose direction aligned with what human raters found interesting, even when those directions did not match theoretical expectations.

All raters agreed that, beyond their specific interest in particular knowledge or motivational measures, one important reason for labeling a pattern as interesting was the surprising direction of the observed association, a finding that helps explain the negative correlation between *theoretical alignment* and *perceived interestingness* in human ratings. For example, one researcher noted: "Things I want to understand (e.g., individual movement followed by racing indicates positive [situational] interest) [were] given a 4 or 5 because I don't know what is happening." As such, metrics such as *Added Value* and *Conviction* appear particularly interesting because they tend to highlight patterns that deviate from researchers' expectations and prompt further inquiry.

However, returning to the specific rule mentioned by the researcher (i.e., Individual Movement → Racing positively correlated with situational interest), this association was positive and statistically significant only when evaluated using *Added Value* and *Conviction* ($\rho = 0.33, p = 0.002$ for both). In contrast, all other metrics in the first cluster (*Support*, *Confidence*, *Jaccard*, *Cosine*, and *ENA* and *ONA Connection Weights*) consistently indicated a negative association. This discrepancy raises an important question: Are the rules highlighted by certain metrics genuinely interesting and meaningful? Or are some pattern mining methods or metrics instead emphasizing misleading associations that are an artifact of their mathematical formulation?

Another result labeled as interesting by the reviewers involved the same behavioral pattern (Individual Movement → Racing) and its positive association with post-test scores. Notably, although this positive association reached statistical significance for only two metrics (*Lift*: $\rho = 0.35, p = 0.03$ and *Added Value*: $\rho = 0.28, p = 0.05$), all pattern mining methods and metrics agreed on the direction of the association. This finding suggests, consistent with the associations among metrics reported in Section 4.1, that pattern mining metrics are not always misaligned, but may also differ in the strength or significance with which they detect the same underlying relationship. In other words, it is perhaps not that any specific metric is "wrong," but rather that greater agreement across metrics increases confidence that an identified correlation or pattern reflects a valid relationship.

This complementarity between metrics helps explain why, although *Added Value*, *Conviction*, and *Lift* often identify correlations that are rated as more interesting, they do not consistently point in the direction that researchers find meaningful. At the same time, nearly all metrics were able to identify at least some correlations that researchers rated as interesting, and all metrics also surfaced correlations whose direction conflicted with researchers' interestingness judgments. These findings indicate that no single metric reliably captures all aspects of what researchers find interesting, and that different metrics emphasize distinct, and sometimes competing, patterns.

5. DISCUSSION AND CONCLUSION

5.1 Overview

Previous work has compared pattern mining metrics with human ratings of perceived interestingness [5]. This study extends that line of research by first examining how metrics from ARM, SPM, ENA, and ONA relate to one another. It then evaluates the consequential validity of each metric by analyzing the patterns they identify with respect to both their associations with external measures of motivation and knowledge and researchers' ratings of *theoretical alignment* and *perceived interestingness*.

Although the metrics analyzed in this study generally highlighted overlapping sets of patterns, our results revealed two broad clusters. The first cluster consists of metrics that tend to emphasize relatively common and theoretically expected patterns, including *Support*, *Confidence*, *Cosine*, *Jaccard*, and *ENA* and *ONA Connection Weights*. In terms of consequential validity, these metrics accounted for the largest number of significant associations with knowledge and motivational outcomes, with *Support*, *Confidence*, and *ENA* and *ONA Connection Weights* proving particularly fruitful. In contrast, the second cluster includes metrics (*Added Value*, *Conviction*, *Phi*, and, to a lesser extent, *Lift*) that place greater emphasis on associations not primarily driven by overall frequency. These metrics tend to reveal patterns that are less theoretically expected and less prevalent overall, but that are, for the same reason, sometimes rated as more interesting by researchers.

5.2 Interpretation

ARM- and ENA-based methods have been widely used to identify the most common event or code sequences in a dataset and their associations with variables of interest in educational research. However, consistent with earlier findings [5, 19], our study shows that different metrics do not always agree and often highlight different patterns. Prior work therefore recommends that researchers proceed with caution, particularly when using metrics that distinguish between patterns driven by high base rates and those that control for base rates to reveal associations beyond statistical independence (e.g., *Cosine*, *Lift*, and *Added Value*; [19]). When metrics disagree, these studies emphasize the need for researchers and instructors to rely on domain knowledge and theoretical judgment when interpreting results.

This emphasis on interpretive value echoes calls in the literature that stress the importance of being able to "close the interpretive loop"—that is, to explain why a particular pattern is associated with

a specific group of students or a given outcome—in order to understand the substantive meaning and real-world implications of observed patterns [27, 29].

Our findings suggest that many patterns judged to be theoretically aligned are driven largely by base rates, raising the question of whether existing theory is truly comprehensive or instead reflects primarily the most frequent patterns, potentially overlooking less common but still meaningful ones. When a pattern appears surprising to researchers, it may simply be incidental. However, if theory has been developed largely from statistical analyses that privilege high base rates, then patterns highlighted by complementary metrics may be particularly valuable for extending and refining theoretical frameworks. From this perspective, moments when different metrics yield associations pointing in opposing directions are especially important. Such discrepancies prompt deeper investigation into what each pattern mining method and metric emphasizes, how the underlying codes, labels, or events are defined, and how researchers, drawing on their theoretical knowledge and intuition [4], can determine whether a result is substantively meaningful or instead an artifact of the mathematical assumptions underlying a given method.

5.3 Limitations and Future Work

An important consideration when interpreting these findings is the granularity of the underlying data. The analyses in this study rely on a coded representation of events derived from a predefined codebook, reflecting a relatively coarse-grained abstraction of learner activity. While this abstraction supports interpretability and alignment with theoretical constructs, it may also mask finer-grained behavioral distinctions that could influence the patterns identified. In datasets with more fine-grained representations (e.g., raw clickstream or low-level interaction logs), the semantic interpretability of resulting patterns depends on how low-level events are defined and contextualized. At the same time, the number of possible itemsets typically increases with a finer granularity, expanding the pattern search space. Consequently, differences in data granularity may influence both the behavior of pattern mining metrics and the types of patterns identified as meaningful or interesting.

As a result, the findings reported here are most directly applicable to contexts in which data have been aggregated into theoretically meaningful categories. The extent to which these results generalize to datasets with different levels of granularity remains an open question. It is plausible that metrics emphasizing frequency (e.g., *Support*, *Confidence*) may identify fewer patterns or prioritize a different set of itemsets and rules in finer-grained datasets, where co-occurrences tend to be sparser and less likely to meet minimum frequency thresholds. In contrast, metrics that control for base rates (e.g., *Lift*, *Added Value*) may still highlight associations that occur infrequently but are stronger relative to their expected occurrence, as they account for the baseline frequency of individual events when evaluating associations. Future work should therefore examine how data representation choices, including levels of granularity and the type of coding scheme, interact with pattern mining methods to shape both statistical results and their interpretability.

Overall, as the field seeks to better understand how empirical methods shape theoretical interpretations (and vice versa), methodological differences represent an important area of inquiry. Our results highlight meaningful differences among metrics commonly used to analyze data patterns in the EDM community and provide empirical evidence regarding which methods may better support consequential validity. Given our findings about which metrics align to human judgments of *theoretical alignment*, future work should further examine the extent to which existing theoretical frameworks might benefit from expansion informed by evidence from metrics that are less likely to produce findings that align with current theory.

Additionally, recent work has proposed the use of *multiverse analysis* [35], in which each plausible analytic decision used to define or refine the problem space gives rise to a separate analysis, or "universe." Although this approach was originally developed to better understand predictive modeling, it could be adapted to incorporate the multiple metrics examined in this study (e.g., ARM and SPM versus ENA and ONA). Such analyses can strengthen confidence in findings that are robust across analytic choices or help clarify why different methods lead to divergent conclusions, thereby informing which approach is most appropriate for a given research question and theoretical framework. Of course, it is rarely feasible to exhaustively explore all possible analytic paths, as illustrated by the fact that our current study does not encompass all available pattern mining approaches. Nevertheless, our results help identify a focused subset of measures (e.g., a small number of carefully chosen metrics from each identified cluster) that could be selected to support such multiverse analyses.

In conclusion, this work compares multiple pattern mining methods and metrics to illustrate how methodological choices can influence findings related to consequential validity, including associations with external learning and motivational constructs as well as expert judgments of theoretical alignment and interestingness. Our results demonstrate that no single metric is sufficient to capture the full complexity of learning phenomena (cf. [32], on explainable AI). Rather than viewing disagreements across metrics as weaknesses to be resolved, we argue that such divergences represent productive tensions that can stimulate deeper inquiry and support theoretical refinement.

ABSTRACT

Personalized instruction aims to provide learners with support that adapts to their individual knowledge. Discovering and tracing Knowledge Components (KCs) is an important step in building accurate models of student learning. However, KC discovery in computer science education is challenging due to the open-ended nature of programming, wide variability in student solutions, and intertwined use of programming structures in code. We address these challenges with a *pattern-based KC* discovery method that uses a data-driven approach to define KCs as recurring structural patterns in student code that reveal persistent patterns of struggle and mastery in students' solutions. We then evaluate the discovered KCs using expert evaluation and statistical student modeling to demonstrate their effectiveness in capturing student learning and struggles. We propose a framework for modeling students' learning by deriving pattern-based KCs from student code through a three-stage process. First, an attention-based code representation model identifies Abstract Syntax Tree subtrees most relevant to code correctness. Second, a Variational Autoencoder abstracts these subtrees into a smooth latent space, capturing structural similarity across student submissions. Third, the resulting representations are clustered into pattern-based KCs. To assess the effectiveness of pattern-based KCs for modeling students' learning, we adapt the Deep Knowledge Tracing model to incorporate these KCs, demonstrating significant improvements in predictive performance over baseline KT methods. Additionally, the learning curve analysis showed alignment between the derived KCs and learning theory.

Knowledge component, Student modeling, CS education, Code analysis, Knowledge tracing

1. INTRODUCTION

Student modeling provides the basis for which adaptive educational systems can track knowledge acquisition, adapt instructional strategies, and provide personalized, targeted support [37]. A central part of student modeling is discovering Knowledge Components (KCs) that students practice during problem-solving. Here, KCs refer to discrete units of acquired knowledge or skill inferred from performance on a set of related tasks [23].

Modeling learning at the KC level involves two steps: task modeling and evidence modeling [3]. An important aspect of task modeling involves specifying the target KCs associated with a given set of learning activities (KC discovery) [37]. Prior work has approached KC discovery through expert-driven design [2], neural approaches that jointly learn latent abstract KCs and their associations with problems from student code while enforcing learning-curve–based constraints [37], and, more recently, Large Language Models (LLMs) that infer candidate KCs directly from instructional content or student work [39, 27, 10]. In evidence modeling, traces of students' problem-solving behavior should be mapped to the discovered KCs to enable effective tracing of their learning progress (KC attribution) [36]. The accuracy of this mapping directly influences the effectiveness of knowledge tracing and learning analytics, and consequently determines how well student knowledge can be modeled and personalized instruction can be delivered.

In domains such as mathematics and chemistry, problem-solving paths are relatively constrained, and KC granularity is often predefined [39]. In computer science (CS) education, however, KC discovery and attribution pose significant challenges due to the context-dependent nature of what constitutes a unit of knowledge, the vast state space of possible solutions to the same problem, the many programming

structures that can represent the same KC, and the interconnected nature of programming patterns [2]. First, there is no agreed-upon ground truth list of KCs for introductory programming courses [37]. Second, the open-ended nature of programming allows for numerous correct implementations; students may solve the same problem using very different structures and strategies, such as recursion vs. iteration or modular decomposition vs. inline logic [33]. Third, even when students use the same programming construct (e.g., a conditional or loop), that construct can serve different conceptual roles depending on context. such as boundary checking, control flow, or decision-making, making it difficult to reliably attribute a single KC. Fourth, the granularity of KCs in programming remains undefined; while low-level constructs like loops and conditionals can be considered fine-grained KCs, high-level KCs often emerge from combinations of these primitives, reflecting more complex problem-solving strategies or conceptual understanding, and can become relevant more over the course of time [22]. Finally, substantial variation in code structure and expression style across student submissions introduces noise into KC attribution, complicating standardized mappings between code and underlying knowledge components. These challenges render expert-driven KC discovery, common in cognitive tutors and intelligent tutoring systems for many fields, and manual KC allocation infeasible for programming education [32].

In response, recent approaches have sought to discover KCs as constructs that students commonly acquire during problem-solving, as reflected in their code submissions over time. Prior work has leveraged code parsers [32, 2], deep learning models [38, 37], as well as LLMs [29, 10] to infer KCs from student code. However, these methods face limitations, including a lack of explainability and limited granularity of discovered KCs, often focusing on programming constructs such as loops or conditionals rather than capturing more nuanced conceptual understanding.

To address these challenges, we propose a framework for automated KC discovery from student programming submissions. Unlike traditional KCs, which are often defined in terms of skill-tags or curriculum objectives, our approach defines KCs as structural patterns, which we introduce as *pattern-based KCs*. These pattern-based KCs are recurring and semantically meaningful subtree patterns extracted from the Abstract Syntax Trees (ASTs) of student code, reflecting programming patterns and algorithmic constructs necessary for correctly solving a programming problem.

Our framework begins with the Subtree-based Attention Neural Network (SANN) [16], trained to predict code correctness while assigning attention weights to relevant AST subtrees [18]. These subtrees are then normalized to remove literal and identifier-specific variance, encoded into a latent space using a Variational Autoencoder (VAE) to generate important patterns from the code and abstract them in a smooth latent space to capture similarities across student submissions. These patterns are then clustered using K-means to form the discovered pattern-based KCs.

To demonstrate how our KC structures can support modeling of student learning, we adapt the Deep Knowledge Tracing (DKT) model [30] to incorporate the discovered pattern-based KCs. Experimental results show that our approach improves student performance predictions when incorporated in the traditional DKT method and produces meaningful learning trajectories, providing a foundation for detecting mastery and guiding instructional decision-making. To further examine the alignment of pattern-based KCs with learning theory, we analyze student learning curves to track mastery development across KCs [32]. Finally, we validate the educational relevance and internal coherence of the discovered KCs through expert evaluation, and illustrate their explainability with a case study tracing a representative KC across multiple problems and student solutions.

The paper has four main contributions. First, we formalize *pattern-based KCs* as a new conceptual knowledge representation in CS education, grounded in recurring and semantically meaningful code structures. Second, we develop a scalable and explainable framework for automatically discovering these KCs from student code submissions via attention-based modeling and representation learning. Third, we demonstrate that integrating pattern-based KCs into a knowledge tracing model significantly improves predictive accuracy of student performance modeling compared to traditional approaches. Fourth, we provide empirical validation of the educational utility and coherence of the discovered KCs through learning curve analysis, expert evaluation, and explainability case studies. These contributions advance explainable knowledge modeling in programming education, enabling more reliable tracking of how students acquire programming skills and providing actionable insights for researchers and educators working on individualized instruction.

2. RELATED WORK

Understanding how learners acquire and apply specific skills is a central goal of educational research, and Knowledge Components (KCs) provide a structured way to represent this learning. We review prior work relating to the conceptualization of KCs and existing methods for their automated discovery, with a focus on programming education.

2.1 Knowledge Components

The concept of Knowledge Components (KCs) is foundational in educational research, particularly within cognitive science and intelligent tutoring systems. KCs are defined as discrete units of knowledge or skills that a learner must acquire to perform a task successfully. They encompass a range of cognitive elements, including concepts, principles, facts, and procedures [23, 32].

The Knowledge-Learning-Instruction Framework [23] further elaborates on KCs by linking them to instructional events and learning outcomes. According to this framework, KCs are the mental constructs that mediate between instructional activities and observable learning behaviors. This perspective underscores the importance of accurately discovering and modeling KCs to enhance instructional design, learning analytics, and develop Intelligent Tutoring Systems [9]. In programming education, defining KCs and determining their appropriate granularity is inherently challenging, as they can range from fine-grained concepts, such as loop initialization, to complex interactions involv-

ing constructs such as nested conditionals within loops, encompassing control structures, data manipulation, and algorithmic strategies. Accurately modeling these components is crucial for developing adaptive learning systems that can provide insights into student knowledge tracing [26], help provide personalized feedback, recommend worked examples, and support to learners [1].

2.2 Knowledge Component Discovery

Automated discovery of KCs from student code has gained attention, aiming to mitigate the labor-intensive nature of manual annotation and to scale personalized education.

Deep learning approaches have been used to model student learning and discover KCs by analyzing code submissions. These AST-based methods leverage the structural representation of code to assign KCs [38, 13, 32]. For instance, the KC-Finder model integrated learning curve theory into its architecture to discover KCs that align with students' learning progression [37]. Although these models can assign KCs, they often suffer from explainability issues, making it challenging to understand the rationale behind KC assignments. Moreover, these approaches may struggle with the semantic understanding of code, especially when different code structures achieve the same functionality, and understanding the granularity and hierarchical nature of different KCs could be challenging.

LLMs have recently been explored for KC discovery due to their ability to understand programming code and generate human-like text. Studies have demonstrated that LLMs can discover KCs from code and problem descriptions [29, 28, 10, 12]. Despite their potential, LLMs can produce overgeneralized KCs, i.e., different conditional structures can not be identified effectively due to a lack of KC taxonomy, or even irrelevant KCs. While manual KC tagging by experts might ensure high accuracy, it is impractical for large-scale applications due to the significant time and effort required [38]. Moreover, inconsistencies among experts can lead to variability in KC definitions, affecting the reliability of the annotations. While automated methods for KC discovery have advanced, challenges remain in balancing accuracy, explainability, and scalability. Our work aims to address these issues by introducing a pattern-based approach that leverages attention mechanisms and clustering techniques to discover meaningful KCs from student code submissions.

3. DATASET

We conduct our work using a publicly available dataset[1] obtained from the CodeWorkout platform [11]. The dataset contains Java programming submissions collected during an introductory CS course offered at a US public university in Spring 2019. In total, the dataset spans 50 programming problems distributed across 5 course assignments, along with students' normalized final exam scores (scaled between 0 and 1). No demographic or personally identifiable information is included in the dataset. Each submission is evaluated based on the number of passed test cases and is assigned a correctness score between 0 and 1. For the purpose of this work, we binarize these labels into correct (all test cases passed) and incorrect (one or more test cases failed) classes. The dataset comprised a total of 47,764 code submissions from 407 students, of which 18,787 were correct submissions and 28,977 were incorrect.

4. METHODOLOGY

We aim to model students' learning progress by discovering KCs as structural patterns in code. We refer to these KCs as *pattern-based KCs*, representing actionable and explainable units that capture students' focal programming knowledge and skills. To discover pattern-based KCs from student code submissions, our approach combines (i) fine-grained signals that pinpoint the code segments most critical for program correctness and (ii) context-aware abstraction that groups structurally distinct yet semantically related implementations under the same conceptual pattern. First, we *extract relevant structural patterns from student programs* using SANN [18], an attention-based model designed for program analysis, which applies hierarchical AST processing and attention scores to reveal which subtrees drive predictions of program correctness. However, SANN is trained to separate programs by correctness and does not strictly learn a continuous latent space where structurally similar subtrees can be clustered together. To address this, we *generate context-aware representations of influential patterns* using a VAE. By reconstructing sequences of high-attention subtrees, the VAE (i) injects broader context, capturing how salient patterns interact within the complete program and across submissions, and (ii) regularizes them into a continuous latent manifold that preserves embedding similarity.

This latent representation provides the basis for *clustering related patterns into distinct pattern-based KCs*. To discover these KCs, we train the VAE to generate representative patterns corresponding to focal programming concepts and skills present in the input AST. Due to the randomness involved in generating programming patterns, multiple patterns might represent the same focal concept and skill. Thus, we apply K-means clustering to group similar patterns into clusters that represent distinct pattern-based KCs. K-means is suitable here since its Euclidean distance assumption aligns well with the smooth, isotropic structure of the VAE model's learned latent manifold. These clusters form the set of pattern-based KCs used in our framework. Finally, we *advance* student modeling by integrating the discovered pattern-based KCs into a Deep Knowledge Tracing model [30], enabling more accurate prediction of student performance. Furthermore, to assess educational relevance, we perform learning curve analysis to test whether the KCs align with established learning theory [32].

4.1 Extracting Relevant Structural Patterns from Student Programs

The first stage of the framework focuses on pinpointing the structural elements in student code that are most critical for program correctness. These elements correspond to programming patterns required to meet problem requirements and are often sources of student difficulty. To extract them, we leverage a modified Subtree-based Attention Neural Network (SANN) [18], an explainable architecture that learns from the hierarchical structure of code and identifies logical errors in incorrect implementations. SANN has been pre-

viously validated across different tasks, including program algorithm classification, detecting LLM-generated code, and recommending relevant worked examples [16, 19, 17].

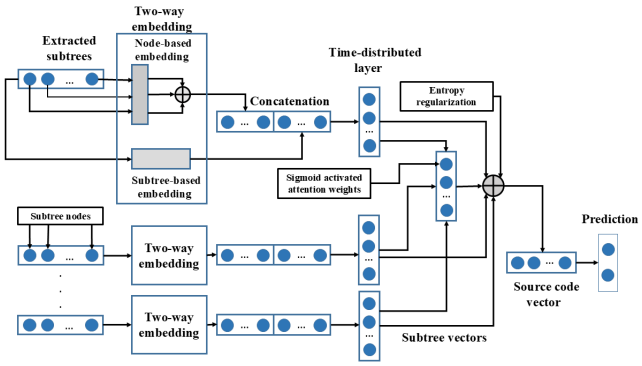

Figure 1: Architecture of the SANN model.

SANN operates on code ASTs by extracting subtrees at multiple depths, which may overlap due to the hierarchical structure of programs. This overlap allows the model to capture coarse-grained constructs (e.g., full conditionals) and fine-grained elements (e.g., comparison expressions) that can independently contribute to correctness [20]. Trained to classify student submissions as correct or incorrect, the model produces attention weights indicating which subtrees most influence predictions (Figure 1). In correct submissions, high-attention subtrees typically represent programming patterns necessary for solving the problem correctly, such as loops, conditionals, or combinations of multiple concepts. In incorrect submissions, high-attended subtrees often reflect logical errors or misconceptions, providing insight into why the submission failed [18].

Within our framework, these high-attention subtrees form the initial candidates for pattern-based KCs. They are carried forward into the next stage, where the VAE abstracts away surface-level variation and organizes them into a latent space suitable for clustering into representative KCs.

4.2 Latent Representation of Candidate KCs

The second stage of the framework uses a β-VAE model [14] to generate latent representations of the most influential programming patterns inferred from student code solutions. These representations form the basis for modeling students' learning over time.

As a first step, we abstract away surface-level syntactic differences, such as specific variable names, literal values, and function identifiers, while preserving the underlying semantic structure. Although such details can be useful for correctness classification, they introduce redundant variation when training the β-VAE and add noise to KC discovery [37]. This abstraction ensures the VAE focuses on the structural and semantic features of code rather than superficial syntactic differences. The normalized ASTs and their associated high-attention subtrees are then used to train the β-VAE model. During training, subtrees are encoded into continuous latent representations and reconstructed, with the model designed so that semantically similar subtrees occupy neighboring regions in latent space. This property enables grouping identified patterns into representative pattern-based KCs. A schematic of the β-VAE architecture is shown in Figure 2.

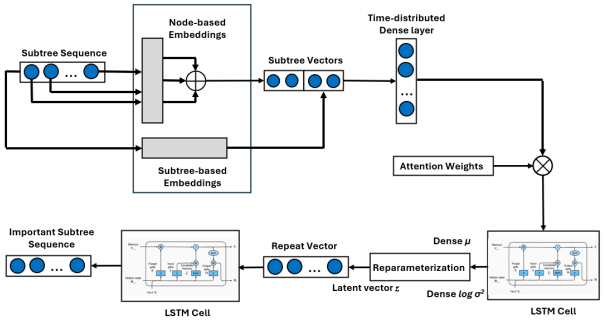

Figure 2: Architecture of the β-VAE model.

To encode subtrees, the VAE model embeds each along two dimensions: the sequence of AST nodes within the subtree and the subtree itself. Node sequences are passed through a time-distributed embedding layer with positional encoding to preserve the relative ordering of nodes within each subtree. This is essential for capturing nuanced structural differences, especially when similar logic is implemented with different nesting or sequencing. The embedded node sequences are then fed into a time-distributed LSTM layer, which compresses each node-level sequence into a fixed-length vector representation.

In parallel, subtree identifiers are embedded and concatenated with the output of the node-level LSTM to form composite embeddings. These combined vectors are then processed by a time-distributed dense layer with a non-linear activation to produce the final subtree representations. To emphasize the most relevant patterns, we scale each vector by the attention weights from SANN, giving greater influence to subtrees most strongly linked to correctness.

The weighted sequence of subtree vectors is passed through an LSTM to capture their sequential order, with dropout applied for regularization. The output is then mapped to two vectors representing the mean, $\boldsymbol{\mu}$, and log-variance, $\log \boldsymbol{\sigma}^2$, of the latent distribution. From these, we sample a latent vector, $\mathbf{z}$, using reparameterization from the distribution:

$$\mathbf{z} = \boldsymbol{\mu} + \boldsymbol{\sigma} \odot \boldsymbol{\epsilon}, \quad \text{where } \boldsymbol{\epsilon} \sim \mathcal{N}(0, I).$$

To ensure the latent space remains smooth and structured, the KL divergence loss is added, encouraging the distribution to stay close to a standard Gaussian:

$$\mathcal{L}_{\text{KL}} = -\frac{1}{2} \sum_{j=1}^{d} \left(1 + \log \sigma_j^2 - \mu_j^2 - \sigma_j^2\right).$$

The decoder reconstructs the original subtree sequence by repeating the latent vector across the sequence dimension and passing it through an LSTM, followed by a dense output layer with softmax activation. Reconstruction loss is calculated using categorical cross-entropy between the predicted and true subtree tokens:

$$\mathcal{L}_{\text{recon}} = -\sum_{t=1}^{T} \log p(\hat{y}_t \mid \mathbf{z}).$$

The total VAE loss is a weighted combination of reconstruction and KL divergence losses, with a tunable parameter β controlling the trade-off:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{recon}} + \beta \cdot \mathcal{L}_{\text{KL}}.$$

Within the framework, the trained VAE builds on SANN by reconstructing the sequences of high-attention subtrees, capturing broader program context that SANN alone cannot. In doing so, it acts as a denoising compressor, generating representative patterns of important subtrees from correct submissions that preserve the essential aspects of program structure. This design also enables the analysis of incorrect submissions: during inference, sequences of subtrees from incorrect code are passed through the model, and those with high attention weights, identified by SANN, are examined as sources of logical errors [18]. The VAE can then suggest corrected structural equivalents for these faulty segments by leveraging both the local context of the faulty subtrees and the global structure of the code. This mapping facilitates the construction of learning curves based on KC mastery, which in turn enables the evaluation of KC models [32]. In this way, the VAE produces structural KC representations that generalize across variation while preserving conceptual integrity, providing the foundation for defining *pattern-based KCs*. The next step is to consolidate these representations into stable and explainable units of knowledge.

4.3 Clustering Pattern-based KCs

The third stage consolidates the previously generated latent representations into representative pattern-based KCs. These KCs serve as abstractions of the minimal functional substructures required to solve a programming problem, independent of surface-level syntactic differences. Clustering is performed using the encoded subtree vectors from the VAE encoder, which embed normalized high-attention subtrees drawn from correct student submissions. Before clustering, we filter out anomalous student behaviors that could distort KC interpretation. Consistent with prior work [15, 37], we observe that some students exhibit suspicious learning patterns, such as frequent failures on simple problems followed by sudden, consistent success on more advanced problems without intermediate improvement. These cases, which may indicate cheating or code sharing, can skew the KC distribution and are therefore excluded to preserve the integrity of the discovery process.

After filtering, we cluster subtree vectors from correct code submissions, which are expected to reflect structurally sound and semantically valid constructs. K-means clustering is used to group subtrees based on their similarity in the learned latent space, under the assumption that subtrees with nearby encodings represent similar underlying knowledge. The appropriate number of clusters is determined via the elbow method, a commonly used heuristic that identifies the point of diminishing returns in the variance explained by additional clusters.

Each cluster defines a pattern-based KC, represented by its centroid as the canonical example of that KC. High-attention subtrees from both correct and incorrect submissions are then assigned to their nearest centroid, linking each to a representative KC. This enables our proposed framework, which provides a consistent and explainable way

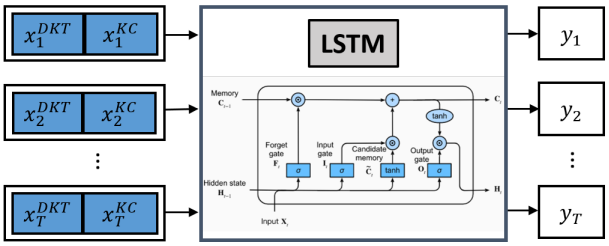

Figure 3: KC-DKT model with pattern-based KC vectors.

to track student learning through code submissions. The presence or incorrect student implementation of a pattern-based KC can be measured across attempts, and the underlying code pattern responsible for the resultant pattern-based KC can be traced back through the pipeline. In doing so, the framework scales automated knowledge modeling in programming education while remaining grounded in structurally meaningful code representations.

4.4 Improving Deep Knowledge Tracing with Pattern-based KCs

We incorporate the discovered pattern-based KCs into the original DKT framework [30] to advance student modeling by providing a more precise representation of learners' knowledge. In DKT, student mastery is modeled as a sequence of interaction events, with the model estimating the probability of success on future tasks. We hypothesize that incorporating more precise KC-level information will improve the performance of DKT and thereby support more accurate tracing of students' learning progress.

Formally, let $S = \{x_1, x_2, \ldots, x_T\}$ represent a sequence of T student interactions. Each interaction x_t corresponds to the student's attempt on a problem at time t, consisting of a problem identifier $q_t \in \{1, 2, \ldots, M\}$ and a correctness label $a_t \in \{0, 1\}$, where M is the total number of unique problems. Following the original DKT formulation, each interaction is encoded as a one-hot vector of size $2M$. Specifically, the element at index $q_t + M \cdot (1 - a_t)$ is set to 1, indicating whether the student answered the problem correctly or incorrectly, and all other elements are set to 0.

In our enhanced model (KC-DKT), the input is extended by incorporating the pattern-based KC mastery vector associated with each submission. This process results in a binary vector of length K, where K is the number of pattern-based KCs. For each submission, this vector encodes the presence (1) or absence/incorrect implementation (0) of each pattern-based KC in the student's solution. The input $\tilde{x}_t$ to the DKT model at time t is constructed by concatenating the original DKT problem-correctness encoding with the KC vector:

$$\tilde{x}_t = [x_t^{\text{DKT}} \parallel x_t^{\text{KC}}].$$

The KC-DKT architecture (see Figure 3), implemented as an LSTM, receives the input sequence $\{\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_T\}$ and outputs predictions $\{y_1, y_2, \ldots, y_T\}$, where each $y_t \in \mathbb{R}^M$ gives the probability of successful implementation on each of the M problems. The predicted probability for the next attempted problem q_{t+1} is obtained from the corresponding

entry in y_t. The model is trained using binary cross-entropy loss and evaluated using the Area Under the Receiver Operating Characteristic Curve (AUC) metric to assess performance in distinguishing correct versus incorrect submissions.

4.5 Educational Utility of Pattern-based KCs

Along with improving predictive knowledge tracing, we assess whether the discovered pattern-based KCs are educationally meaningful and suitable for modeling student learning. We evaluate this along three dimensions: learning curve analysis to check alignment with learning theory, an explainability case study, and pedagogical coherence through expert evaluation of KC clusters.

4.5.1 Learning Curve Analysis

Learning curve analysis is a standard approach for evaluating whether inferred knowledge components align with the learning trajectory of student knowledge over time. Following conventions in programming education research [32, 37, 2], we define an *opportunity* as a student's first attempt on a problem that exercises a given KC. Restricting to first attempts reduces the confounding effects of feedback or guessing in later submissions. For each pattern-based KC, we compute the average error rates across increasing opportunity counts and analyze the resulting learning curves. KCs that display a downward error trend with increasing practice are categorized as *good learning*, while flat or erratic curves suggest *still-learning* or *no-learning* [32, 37]. These profiles indicate whether the discovered KCs align with the learning theory and provide a basis for instructional interpretation.

4.5.2 Evaluating Pattern-based KC clusters

To validate whether the discovered pattern-based KCs are pedagogically meaningful and internally coherent, we conducted a structured expert evaluation of the KC clusters. For each cluster, a representative medoid pattern was selected (the subtree closest to the cluster center in latent space) and sampled ten additional patterns from the same cluster. To ensure robustness, five patterns were selected based on proximity to the medoid and five based on proximity to the cluster centroid using cosine similarity.

Three expert evaluators in programming education assessed each cluster. Evaluators first judged whether the medoid represents an important programming pattern that students should learn in introductory programming courses (educational utility). They then compared each candidate pattern to the medoid, judging whether it reflected the same underlying programming idea (conceptual consistency) and how similar the pattern's operation on program state or control flow was to that of the medoid (action-level similarity) on a scale of 1 to 4 (1: Completely different/unrelated action, 2: Related action, with weak relationship, 3: Same action type, minor variation, and 4: Same action type and same role). Evaluators were instructed to focus on conceptual intent and control structure (e.g., branching, iteration, accumulation), while ignoring superficial differences such as variable names, formatting, or literal values.

To establish reliability, all evaluators independently annotated an initial 10% of the clusters. Inter-rater agreement on this subset was perfect for judgments of educational utility and conceptual consistency, and exceeded 0.92 for action-level similarity. After resolving minor disagreements and aligning interpretations, the remaining clusters were divided among evaluators and annotated independently. This protocol provides an external validation of both the educational relevance and coherence of the pattern-based KCs.

4.5.3 Explainability of Pattern-based KCs

To examine the explainability of the discovered pattern-based KCs, we conducted a case study tracing a representative KC across multiple problems and student submissions. Using the projection of attention-weighted subtrees back onto source code, we annotated the portions of students' code associated with the KC in both correct and incorrect attempts. This procedure enabled us to follow how a single KC manifested in successive student submissions and across different problems, providing a basis to evaluate whether the KCs capture consistent and reusable conceptual patterns.

5. EXPERIMENTS

We evaluated the proposed framework by training each component in sequence and examining its ability to discover meaningful pattern-based KCs from student code. The experiments proceeded in three stages: training the modified SANN model to identify code substructures most relevant to program correctness, learning a latent representation of these subtrees with a β-VAE, and clustering the resulting embeddings into representative KCs. The resulting set of KCs was then used for downstream analyses, including integration into a KC-enhanced DKT framework and learning curve evaluation. On average, each programming problem was associated with about 24 KCs (23.68, SD = 6.02), each student submission involved roughly 4 KCs (3.87, SD = 1.56), and each KC was observed across approximately 25 problems (25.36, SD = 17.28), indicating broad coverage of programming constructs throughout the dataset.

In the first stage, we trained the modified SANN model to classify Java submissions as correct or incorrect while assigning attention weights to AST subtrees. The full dataset, consisting of 18,787 correct and 28,977 incorrect submissions across 50 problems, was split into training, validation, and test sets with an 80:10:10 stratified split to preserve label proportions. The model was trained using a code embedding size of 128 with a maximum of 100 nodes per subtree and 100 subtrees per program, for up to 100 epochs with an early stopping patience of 20. We used the Adamax optimizer with a learning rate of 0.001 and minimum entropy regularization weight of 3×10^{-5} to guide the attention mechanism without compromising classification performance. The trained model achieved high scores across all evaluation metrics: accuracy (0.87), precision (0.86), recall (0.88), and F1-score (0.87), confirming its ability to capture correctness-related structural patterns. Attention weights and associated subtrees were extracted for the next stage.

In the second stage, we filtered subtrees with attention weights above 20%, following the original study of this model [18]. From this filtering, we obtained a total of $78,647$ important subtrees from correct submissions and $132,658$ important subtrees from incorrect submissions. Identifier tokens were normalized to reduce surface variation, and a β-VAE was trained exclusively on high-attention

subtrees from correct code to ensure that the latent space reflected valid and pedagogically meaningful structures. The VAE used a subtree embedding size of 64, latent dimension 128, intermediate dense layers matching the embedding size, dropout rate 0.2 (to prevent overfitting), and was trained for up to 30 epochs (patience 10) with Adamax optimizer (lr $= 0.001$) and $\beta = 1 \times 10^{-2}$ to balance reconstruction fidelity with latent space regularization. The VAE achieved 95% reconstruction accuracy across all tokens, though only 10% when considering important subtrees in isolation. This lower score was expected, since the objective was not perfect reconstruction but learning a latent embedding space where structurally similar subtrees are mapped to nearby regions [14]. In practice, the VAE compressed $11,953$ unique subtree patterns into 106 unique representative outputs, demonstrating its ability to compress and abstract fine-grained structural variations. To validate semantic alignment, we compared cosine similarity scores between predicted and input subtrees using CodeT5 (pretrained programming language model, 220 million parameters) embeddings [40], against a randomized baseline. Our proposed approach achieved a significantly higher mean similarity score of 0.96 (standard deviation 0.03) compared to the randomized baseline's mean similarity of 0.85 (standard deviation 0.04) between the input and predicted representative subtrees. A statistical test confirmed that the difference between the two distributions was significant with a *p-value* of 0.0001.

In the final stage, we clustered the VAE-generated subtree vectors into distinct pattern-based KCs using K-means. Only high-attention subtrees from correct submissions were considered, ensuring that clusters reflected valid programming patterns. The elbow method indicated an optimal cluster count of $k = 50$, balancing granularity with interpretability. Each subtree vector was assigned to its nearest cluster center, with the centroid serving as the representative pattern for that KC. Both correct and incorrect subtrees were then mapped to their closest KC, enabling downstream analyses of student performance at the KC level. This process produced a set of 50 structurally coherent and pedagogically grounded KCs extracted directly from student code, providing a foundation for the subsequent integration into our KC-DKT model and learning curve evaluation.

6. RESULTS

In this section, we evaluate the proposed pattern-based KC framework from three complementary perspectives. First, we examine whether the discovered KCs improve predictive student modeling through knowledge tracing. Second, we assess whether the KCs exhibit learning dynamics consistent with learning theory via learning curve analysis. Finally, we validate the educational relevance and internal coherence of the KC clusters through an expert evaluation.

6.1 Deep Knowledge Tracing

To demonstrate that our discovered pattern-based KCs improve on previous approaches to modeling and predicting student learning over time, we integrated them into the original DKT model [30]. Unlike previous approaches that used raw code vectors as input to the DKT model [18, 35], our *KC-DKT* model incorporated a mastery vector that encodes, for each of the 50 discovered pattern-based KCs, whether it was correctly demonstrated in a student's submission.

Table 1: Knowledge tracing AUC (%) averaged over 10 runs with different random splits. *($p < 0.01$), **($p < 0.001$) indicate significant improvements of KC-DKT over DKT.

Model	A1	A2	A3	A4	A5	All
BKT	61.6	57.5	54.1	56.3	53.2	56.5
DKT	71.2	73.1	76.8	69.2	75.1	65.9
Code-DKT	74.3	76.6	80.4	72.8	79.1	-
KC-DKT	**82.4****	**77.6***	**80.8***	**82.0****	**85.4****	**74.8***

Our KC-DKT model was trained to predict whether the student would succeed on the next attempt based on their KC state history. To make the evaluation fair, we split the dataset at the student level using an 80:10:10 ratio for training, validation, and testing, ensuring no overlap between students across splits. Hyperparameter optimization was performed using Keras Tuner. The best performing configuration used an LSTM layer with 512 hidden units, a dropout rate of 0.1, and a learning rate of 0.01. Our KC-DKT model using pattern-based KC vectors achieved an AUC of 74.77%, outperforming the original DKT baseline [30], which achieved an AUC of 65.87%. Assignment-wise breakdowns of AUC scores are provided in Table 1, along with a comparison with Bayesian Knowledge Tracing (BKT) [4] and Code-DKT [35], which uses AST-derived code vectors for single assignments.

These results highlight the strength of our pattern-based KC representation for knowledge tracing. The approximately 13% improvement over the original DKT represents a substantial gain relative to previously reported extensions of knowledge tracing models that incorporate code-level representations, which have typically yielded smaller or more incremental improvements in their respective evaluation settings [35, 18, 8]. Having demonstrated predictive advantages, we further examine whether the discovered KCs align with learning theory by analyzing student performance trajectories through learning curve analysis.

6.2 Learning Curve Analysis

We next evaluated the discovered pattern-based KCs using learning curve analysis to test whether the KCs align with expected trends from learning theory [37, 32, 12, 2]. A learning curve reflects improvement over repeated opportunities to practice a KC, typically showing a decline in error rate as mastery increases. Following prior work in knowledge tracing [34, 4], we considered only the first submission of each student per problem to avoid confounds from debugging or superficial edits. For each KC, we then computed the average error rate across sequential opportunities, where an opportunity was defined as a student's encounter with code involving that KC.

We observe that the learning curves showed three qualitatively distinct trends [32, 12] (Figure 4). The majority, 35 out of 50 pattern-based KCs, showed a steady decline in error rates, which we denote as *good learning*. The learning curves exhibit the expected behavior of a steady decline, indicating that students gradually acquire mastery over these

patterns through repeated exposure, with these KCs appearing in an average of 20 problems each (see Figure 4a).

A second group of clusters, 10 out of 50 pattern-based KCs, labeled *high error/still learning*, also trended downwards but showed fluctuations in later opportunities before eventually decreasing (see Figure 4b). This trend likely reflects the difficulty and recurrence of these patterns across problems. Many of these KCs involve complex conditional structures, such as nested conditionals and complex Boolean expressions, appearing in about 30 problems per KC.

Finally, 4 clusters fell into the *no learning* category, where error rates remained high across opportunities (see Figure 4c). These patterns often combined multiple structural elements or appeared in highly variable set of problems (mean number of problems per KC: 37). Such "no learning" curves are not unique to our approach but occur in KC modeling more generally, reflecting challenges in reliably measuring genuine learning progress amid noise [32]. Apart from these categories, one additional cluster lacked sufficient opportunities to generate a reliable curve.

Overall, the learning curve analysis demonstrates that our pattern-based KCs capture meaningful differences in how students acquire and apply programming patterns. Unlike traditional knowledge tracing over predefined skills, this approach tracks mastery of recurring structural patterns directly from student code, revealing whether students steadily improve, struggle intermittently, or persistently fail on specific programming patterns. These findings reinforce the validity of the KC model and motivate our ablation study presented in the following section.

6.3 KC Model Comparison and Ablation Study

To further evaluate the effectiveness of our proposed framework, we tested its ability to explain and predict student performance within the Additive Factors Model (AFM) [7, 24]. The AFM estimates the probability of a correct response as a function of KC-specific intercepts and learning rates by fitting logistic learning curves. Following prior research [37, 2], we compared the performance of our KC model against two common baselines: the single-KC model, which treats all submissions as practicing the same KC, and the item-KC model, which assigns each problem its own KC. Model performance was evaluated using three metrics: Akaike Information Criterion (AIC), Bayesian Information Criterion (BIC), and Root Mean Squared Error (RMSE). Lower AIC and BIC indicate better fit, with BIC applying a stronger penalty for model complexity, while RMSE reflects average prediction error.

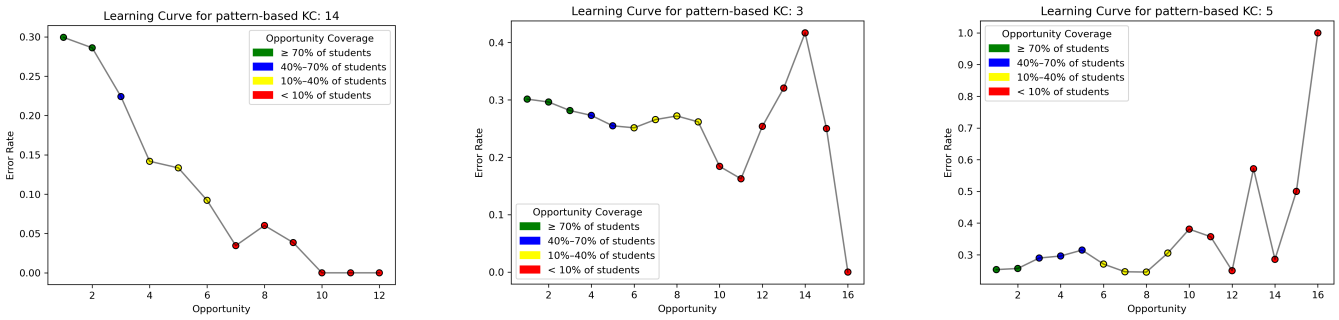
We also conducted an ablation study to isolate the contribution of our combined approach, including the SANN and β-VAE pipeline. Two additional baselines were tested: (i) replacing the VAE model by using embeddings from a large programming language model, jina-code-embeddings (1.5b parameters) [25], (ii) replacing the VAE model with a fine-tuned CodeT5 model (pretrained programming language model, 220m parameters) [40], using its encoder output in the clustering step and (iii) removing the VAE entirely and clustering directly on the SANN-generated embeddings.

Table 2: KC model comparison (↓ = lower is better).

Model	AIC ↓	BIC ↓	RMSE ↓
Single KC	60,327.41	60,344.95	0.50
Item KC	57,496.26	58,372.99	0.48
jina-code-embeddings	60832.70	61704.36	0.48
CodeT5-based KC	57,300.44	58,155.97	0.47
SANN-based KC	47,941.18	48,737.84	0.40
Pattern-based KC	**39,319.73**	**40,196.47**	**0.35**

As shown in Table 2, our pattern-based KC model outperformed all baselines. It achieved lower AIC and BIC values, indicating better model fit with appropriate complexity, and a lower RMSE, demonstrating improved predictive accuracy of student performance. These results suggest that our framework provides a more accurate and effective representation of KCs compared to traditional skill-attribution or direct embedding strategies. We next examine the explainability of pattern-based KCs, focusing on how the framework surfaces the code structures underlying each discovered KC.

6.4 Pattern-based KC Cluster Evaluation



While predictive performance and learning curve behavior provide indirect evidence of KC quality, it is also important to verify that the discovered clusters correspond to educationally meaningful and internally coherent programming patterns. To this end, as described in Section 4.5.2, we conducted an expert evaluation of 35 pattern-based KC clusters, which showed a clear learning trend. The expert evaluation results indicate that the discovered pattern-based KCs are both educationally meaningful and internally consistent. All evaluated cluster medoids (100%) were judged to represent important programming patterns appropriate for introductory programming instruction. These medoids commonly captured reasoning patterns such as compound conditionals, guarded logic, accumulator updates, and loop–condition interactions, suggesting that the clustering process consistently surfaces instructionally relevant concepts rather than trivial or boilerplate code fragments.

Cluster consistency was also high. Across all clusters, 97.7% of candidate patterns were judged to express the same underlying programming idea as their corresponding medoid, despite syntactic variation and differences in problem context. In addition, candidate patterns showed strong similarity in how they manipulated program state or control flow, with an average action-level similarity score of 3.7 (std = 0.65) on a 1–4 scale. The high mean is expected, as candidate patterns were sampled from within-cluster neighborhoods around each medoid, and the goal of this evaluation was to assess cluster coherence.

Altogether, the proposed framework yields stable pattern-based KCs. The resulting clusters align with important programming constructs and form coherent units for downstream analyses, including knowledge tracing, learning curve evaluation, and explainable feedback generation.

6.5 Explainability of Pattern-based KCs

A central goal of our framework is not only to model performance but also to make visible the reasoning behind predictions, toward actionable feedback. To do so, we project

(a) Good learning (b) High error / still learning (c) No learning

Figure 4: Representative learning curves for 'good learning', 'high error/still learning', and 'no learning' trends. Node colors indicate opportunity coverage: the percentage of students who encountered the KC at a given opportunity.

public int sortaSum(int a, int b)
{
    int answer = 0;
    if ((a + b) < 10 && (a + b) > 19)
    {
        answer = a + b;
    }
    else
    {
        answer = 20;
    }
    return answer;
}
```

(b) Attempt 2 (incorrect, sortaSum)

```
public int sortaSum(int a, int b)
{
    int answer = 0;
    if ((a + b) < 10 || (a + b) > 19)
    {
        answer = a + b;
    }
    else
    {
        answer = 20;
    }
    return answer;
}
```

(c) Attempt 3 (correct, sortaSum)

```
public boolean in1To10(int n, boolean outsideMode)
{
    if (outsideMode)
        if (n <= 1 || n >= 10)
            return true;
        else
            return false;
    else
        if (n >=1 && n <= 10)
            return true;
    else
            return false;
}
```

(d) Correct, int1To10

Figure 5: KC 42 across problems. (a–c) show three sequential attempts on the *sortaSum* problem, where KC 42 is incorrectly (a–b) and then correctly (c) implemented. (d) shows a correct implementation of the same KC in the *int1To10* problem.

attention-weighted subtrees back onto source code and label each span with its associated pattern-based KC. This process reveals the syntactic constructs driving the model's decisions, allowing for precise diagnosis of misconceptions.

Figure 5 illustrates this process using pattern-based KC 42, which governs the correct use of compound comparison and logic operators in conditional expressions. In a sequence of three attempts on the *sortaSum* problem, a randomly selected student first mis-implements KC 42, misapplying `&&` instead of `||` (Figures 5a, 5b); the model highlights the faulty condition in red. In the third attempt (Figure 5c), the student corrects the logic, and the highlight persists, indicating the KC remains relevant while now being mastered. Figure 5d shows another instance of KC 42 in a correct submission for the *int1To10* problem, where students must reason about boundary conditions. Despite the different problem context, the conditional again reflects KC 42, validating its conceptual consistency across problems and representing how our framework discovers reusable conceptual patterns that extend beyond individual assignments.

These visualizations show how our framework links model predictions to code structures, making visible the constructs that drive performance outcomes. They also demonstrate the cross-problem consistency of pattern-based KCs, showing that the same conceptual pattern can be recognized across different assignments. In this way, the framework not only clarifies individual predictions but also represents reusable knowledge structures that make KC tracking more generalizable and pedagogically meaningful. Having established the validity and utility of pattern-based KCs, we discuss their implications for student modeling, programming education, and future research in the following section.

7. DISCUSSION

This work set out to address the challenge of defining and modeling knowledge components in introductory programming, a domain where solution paths are highly variable and traditional skill lists are difficult to specify. We introduced *pattern-based KCs*, defined as recurring structural patterns in student code that represent the programming constructs involved in solving problems.

To operationalize this definition, we developed a pipeline to discover pattern-based KCs from student code submissions. Using the SANN model, we identified AST substructures most relevant to code correctness. These substructures were then abstracted with a variational autoencoder (VAE) to capture structural similarities across submissions and clustered into representative KCs. The resulting set of pattern-based KCs advances student modeling by enabling

knowledge tracing at a more fine-grained level of learner behavior. Our proposed KC-DKT model improved predictive performance by more than 13% over the original DKT model, and learning curve analysis further confirmed that the discovered KCs align with established learning theory. In addition, an expert evaluation of the clusters found that all medoid patterns were judged educationally useful and that within-cluster samples showed high conceptual and action-level consistency, providing evidence that the extracted KCs correspond to coherent instructional units.

Our approach offers several advantages over traditional methods. The integration of SANN provides transparency by enabling visualization of attention weights on specific code structures, allowing educators to understand and inspect each KC. Moreover, each KC can be traced back to the original student code patterns, supporting explainable, transparent practices for AI in education. This stands in contrast with existing deep learning and LLM-enabled approaches for KC discovery, which often operate as black boxes for KC definition and attribution. Additionally, clustering of the VAE-generated AST substructures captures a wide range of programming patterns, from simple granular patterns to complex logic. This breadth reflects the diversity of student solution strategies and ensures that the resulting KCs capture the full spectrum of patterns students use in practice, enabling more precise modeling of student knowledge in CS education.

These findings have direct implications for adaptive learning systems. By accurately modeling student mastery at the KC level in submitted code, our approach facilitates real-time feedback on specific coding patterns, enabling personalized learning approaches in CS education [9]. For example, with the identification provided by our approach, if a student consistently struggles with a particular loop construct, an adaptive learning system can provide targeted exercises or resources associated with that pattern to address this gap [1]. Pattern-based KCs can also inform content recommendation engines, guiding the selection of problems [6] or worked examples [21] that align with their current knowledge and learning needs.

Beyond individual feedback, aggregated KC-level data can help instructors identify which patterns are most challenging across a cohort, informing curriculum adjustments and instructional focus. Over time, this integration of KC analytics into adaptive platforms can create a feedback loop between student performance data and instructional design, ensuring that learning environments adapt to address the most persistent knowledge gaps. In this way, our work connects automated KC discovery with practical instructional use, providing an explainable and scalable framework for modeling student learning in CS education.

8. LIMITATIONS AND FUTURE WORK

The results demonstrate the effectiveness of discovering pattern-based KCs from AST structures with attention-based modeling, although there are limitations that can be addressed through future research. First, because the dataset does not include demographic or background information, we are unable to analyze potential differences in KC distributions or learning trajectories across student subgroups; examining fairness and generalizability across populations is an important direction for future work. Second, our method relies on successful AST parsing, which excludes uncompilable submissions (15% of the dataset) and removes potentially valuable data related to misconceptions or syntax errors [37, 18]. Future work could incorporate error-tolerant parsers or automated syntax-error repair tools that can handle uncompilable code [31].

Moreover, our evaluation followed standard practice in knowledge tracing by focusing on first submission attempts to avoid noise from feedback-driven debugging. While this reduces bias, it also limits the ability to study repeated practice effects for KCs. Modeling post-first-attempt behavior, and distinguishing genuine skill development from surface-level fixes [5], is an important next step. Another limitation of the current work is that all code representations are learned solely from the CodeWorkout dataset, without leveraging large pretrained code models or large language models (LLMs) to warm-start token or node embeddings. While this design choice allows the discovered pattern-based KCs to remain tightly grounded in course-specific student behavior, it also constrains the representational capacity of the model, particularly given the relatively modest size of the dataset. Pretrained code embeddings have been shown to capture broad syntactic and semantic regularities across diverse programming contexts, which could improve generalization and stability of learned representations. An important direction for future work is therefore to initialize node- or subtree-level embeddings using pretrained code representations (e.g., from LLMs or large-scale code models), followed by fine-tuning on course-specific student data. More broadly, the framework could benefit from a two-stage training strategy in which models are pretrained on large, heterogeneous programming corpora and then adapted to individual courses or assignments, enabling the discovery of both general programming patterns and course-specific KCs. Hybrid pretraining–fine-tuning approaches may further improve the robustness, scalability, and transferability of pattern-based KC discovery.

Another important direction for future work should be the generation of natural language descriptions for the discovered pattern-based KCs. Currently, KC representations exist as structural subtrees, which may not be easily interpretable by novice learners or instructors. Using the natural language generation capabilities of large language models, future work could generate human-readable explanations or summaries of each KC. Further, integrating these KCs into a recommendation system for CS1 courses that provides targeted practice problems and worked examples could enable our framework to model student knowledge and actively support learning in real time. This would further enhance the accessibility, pedagogical utility, and feedback generation potential of our framework in educational settings.

9. CONCLUSION

In this work, we presented a framework for discovering pattern-based KCs from student programming submissions by combining the SANN model, a variational autoencoder, and clustering. We evaluated the resulting pattern-based KCs through integration with DKT, which produced significant improvements in predictive performance, and through

learning curve analysis, which confirmed their alignment with learning theory. Our approach advances knowledge modeling in CS education by providing scalable, structurally grounded representations of student understanding. Beyond predictive modeling, these KCs also create opportunities for targeted practice, adaptive feedback, and personalized instructional support in programming education.

Personalization in Educational Data Mining and Learning Analytics: A Systematic Review (2015 - 2025)

Sylvio Rüdian
Humboldt-Universität zu Berlin
Department of Computer Science & Education
Berlin, Germany
ruediasy@hu-berlin.de

ABSTRACT

Personalization is widely recognized as a path toward more effective digital learning; however, its conceptual and methodological treatment varies across different research traditions. This study systematically synthesizes a decade of work (2015 - 2025) in the Educational Data Mining (EDM) and Learning Analytics & Knowledge (LAK) communities employing the PRISMA framework to clarify how personalization is enacted and evaluated. We compile and screen 503 papers to isolate those that implement learner-level adaptation, coding what is personalized, the indicators that drive it, and how studies assess its impact. A mixed quantitative-qualitative analysis compares the two communities, highlighting distinct emphases, recurring methodological challenges, and complementary strengths. The review provides an integrated map of personalization research, identifies persistent gaps in validity, adoption, and causal evidence, and outlines opportunities for cross-fertilization between technically focused EDM models and human-centered LAK practices.

Adaptive Systems, Intelligent Tutoring System, Review

1. INTRODUCTION

Personalization has long been one of the most compelling promises of digitally mediated learning: the idea that learning material, feedback, and support can be adapted to meet the needs of individual learners rather than delivered as one-size-fits-all instruction. Over the past decade, this promise has been intensively investigated by two closely related research communities: Educational Data Mining (EDM) and Learning Analytics and Knowledge (LAK). They share many data sources and venues but often differ in theoretical commitments, methodological preferences, and the artifacts they produce [13]. As algorithmic techniques for sequential decision making and representation learning matured, and as institutions deployed analytics tools to support teachers and students, the term "personalization" became diverse. Yet it is used to describe a wide variety of interventions, from reinforcement-learning policies that select the "next best" activity to dashboards that help instructors tailor feedback. Without a careful, comparative map of how EDM and LAK operationalize personalization, it is challenging to synthesize evidence, identify gaps, or chart a coherent course of action.

The similarities and differences between LAK and EDM have been extensively examined in the scholarly literature. Both fields operate within the educational domain, leveraging data collection and analysis to improve learning processes and student outcomes. They share a commitment to data-driven approaches for understanding and enhancing education, frequently utilizing overlapping datasets and tasks such as predicting student performance or identifying at-risk learners [22]. Both LAK and EDM exploit large-scale educational data, employ statistical and machine learning techniques, and aim to transform raw data into actionable insights for educators, students, and administrators. Core methodologies such as classification, clustering, and prediction are widely used in both areas, reflecting their shared origins in the computational analysis of educational environments [32].

Despite these commonalities, LAK and EDM differ in methodological orientation and epistemological emphasis. EDM has traditionally focused on the development of novel computational techniques to interrogate educational data, often emphasizing model-driven approaches such as association rule mining, clustering, and predictive modeling. In contrast, LAK integrates a broader range of methods, including visualization, social network analysis, and statistical modeling, while maintaining a strong emphasis on the practical application of analytics to enhance learning and teaching. LAK scholarship frequently highlights the human and organizational dimensions of education. The two fields are therefore proximate yet complementary: EDM has historically concentrated on model- and policy-centric questions - such as how to represent latent knowledge, predict academic success, or optimize instructional decisions under uncertainty - whereas LAK has invested heavily in human-centered analytics, focusing on making data interpretable and actionable for learners, teachers, and institutions through feedback, visualization, and participatory design. Both perspectives are indispensable for advancing credible personalization at scale. Algorithmic policies lacking usability, transparency, or alignment with pedagogical practice are unlikely to succeed in authentic educational contexts, while well-designed

dashboards that lack empirically validated adaptive mechanisms risk becoming well-intentioned but ineffective advice systems. A comparative perspective thus illuminates areas of conceptual convergence, points of productive methodological divergence, and opportunities for cross-fertilization that could accelerate progress in the field. Recent bibliometric studies further indicate that LAK typically pursues research with the explicit intent of improving learning actions and environments, whereas EDM is more strongly oriented toward understanding learning behaviors through algorithmic analysis [32]. However, a focused comparison of how the two communities conceptualize and operationalize personalization remains absent.

2. FROM ADAPTATION TO PERSONALIZATION

Personalization is widely invoked in digital learning, yet the term is used inconsistently across research traditions and is frequently conflated with adjacent concepts such as adaptation and customization. Because this paper compares personalization work across EDM and LAK, we require a definition that is conceptually defensible, broad enough to cover both communities' artifacts, and precise enough to support coherent interpretation of results.

Because our aim is to compare two communities whose personalization artifacts range from fully algorithmic decision policies (e.g., sequencing and recommendation) to teacher- and learner-facing tools (e.g., dashboards and feedback systems), we adopt a definition that is simultaneously inclusive and boundary-setting. Specifically, we require a framing that (a) is broad enough to cover both automated and human-in-the-loop instantiations of individualized support, (b) excludes changes that are applied uniformly at the cohort or course level (i.e., adaptation without differentiation between learners), (c) distinguishes system-driven personalization from user-initiated customization, and (d) is operationalizable for transparent screening and coding. This emphasis on codeability matters for a comparative review: without explicit decision rules, the term "personalization" risks collapsing into a rhetorical umbrella, making it difficult to interpret patterns across venues or to attribute differences to real methodological or conceptual divergence rather than to definitional drift.

We begin with the general notion of *adaptation*. In dictionary terms, adaptation denotes modifying an artefact, process, or environment so that it suits a new purpose or situation, and an *adaptive* system is one that can change in response to varying conditions [86]. These definitions are intentionally broad: adaptation can occur at multiple levels (individual, subgroup, course, or institution) and can be enacted by humans, algorithms, or both. In educational contexts, this breadth is reflected in uses of "adaptation" that range from optimizing the fit between learning requirements and course content [61] to broader forms of adjustment such as shifting instructional delivery modes or transferring courses across settings [34]. Such interventions involve change in response to context, but they are not necessarily individualized.

Personalization is a narrower, person-centered form of adaptation. Building on the Oxford framing, we use personalization to refer to tailoring content, processes, or interfaces to the needs of a particular individual [86]. The key differentiator is the *target of the adaptation*: personalization aims to differentiate the learning experience between learners rather than to adjust an experience uniformly for a cohort. This individualized focus is prominent across multiple strands of the literature. Work on adaptive hypermedia and web-based learning has long framed personalization as selecting and presenting information based on learner models [17, 18]. In online course settings, personalization is often instantiated as individualized sequencing or learning-path construction, where the system selects activities or resources based on learner prerequisites or performance [90, 8]. In the broader discourse of "personalized learning", personalization is frequently described as optimizing pace and approach to the learner, encompassing learning objectives, instructional strategies, and the sequencing of content [85, 8]. Related accounts emphasize motivational and competency dimensions [37] or characterize personalization along practical axes such as goals, path, time, place, and pace [10]. Although these formulations vary in granularity and pedagogical emphasis, they converge on the principle that instructional decisions should depend on learner-specific information rather than being uniform for all learners.

A second distinction concerns *locus of control*. Whereas personalization and adaptation are commonly enacted system-side (often implicitly through models or rules) *customization* refers to changes initiated by users based on explicitly specified preferences [86, 93]. Customization can contribute to individualized experiences, but it differs from personalization in who specifies the change and how it is triggered. This distinction is especially relevant for learning systems, where personalization is frequently implemented without explicit learner requests (e.g., through adaptive sequencing, recommendations, or tailored feedback).

This paper uses *personalization* to denote **individual-level, person-centered adaptation** of the learning experience, distinguished from broader adaptation by its learner-specific target and from customization by its system-side locus of control. This definition supports a consistent interpretation of the diverse mechanisms labeled as personalization in EDM and LAK, ranging from sequencing and recommendation to dashboards and feedback systems, while avoiding conflation with non-individualized course-level adjustments.

3. THIS REVIEW

This review provides a structured, side-by-side account of personalization research in EDM and LAK from 2015 to 2025. Rather than treating "personalization" as a rhetorical label, we treat it as an operational construct: an intervention that adapts some aspect of the learning experience to an individual learner (or to explicitly defined learner subgroups) using learner-specific information. The contribution of the paper is therefore integrative rather than algorithmic: it offers an auditable comparative map of how personalization is instantiated across two influential communities, the types of signals used to drive it, and the kinds of evidence used to justify impact. We do not aim to produce a pooled effect size of "whether personalization works"; instead, we clarify what counts as personalization in this literature and characterize where each community concentrates its efforts

and how strongly those efforts are tied to outcome-focused evaluation.

Building from the operational definition, we distinguish (i) what is personalized (e.g., task sequencing, recommendations, feedback, dashboards, assessment criteria), (ii) which indicators are used to drive adaptation (behavioral traces, knowledge-state estimates, text, demographics/context, affect/motivation), and (iii) which techniques implement it (reinforcement learning, BKT / IRT and related cognitive models, recommender algorithms, supervised ML, deep learning, visual analytics, rules, and qualitative / UX / co-design). Because personalization claims often risk conflating usage with learning, we also attend to evaluation designs and explicitly differentiate studies that measure effects on learning outcomes from those that report only process, engagement, or usability, treating process measures as outcomes only when a study provides an explicit validity argument that they are learning-proximal in context.

Two additional considerations motivate a careful synthesis at this time. First, the proliferation of powerful modeling techniques, contextual bandits and deep reinforcement learning, sequence-aware recommenders, and transformer-based approaches for text and multimodal traces, has increased the feasibility of fine-grained adaptation while raising the stakes around fairness, privacy, and explainability. Second, institutions and platforms are deploying analytics at scale, creating opportunities for rigorous evaluation (e.g., pragmatic trials, stepped-wedge designs) while also exposing persistent gaps in construct validity and generalizability across courses and populations. A review that connects what is being personalized to how it is decided and what evidence supports it can help the field move beyond isolated successes toward dependable practice.

Our contribution is threefold. First, we build a transparent corpus by identifying LAK and EDM papers that mention personalization (2015–2025), then screening for studies that are substantively about personalization rather than merely naming it. This keeps the review focused on instantiated mechanisms rather than aspirations. Second, we extract a common set of variables from the included studies, definitions, targets of personalization, indicators, techniques, contexts and scales, evaluation designs, and reported limitations/future work, and organize papers into interpretable clusters defined by the object of personalization, yielding community-specific profiles that can be compared directly. Third, we use those profiles to answer a compact set of research questions that address where each community focuses its personalization efforts, which signals it relies on, and what gaps remain most salient for future work.

We structure the inquiry around three research questions that bridge description and critique:

RQ1: In studying personalization, where do EDM and LAK place their main focus, and how do those foci differ?

RQ2: Which learner- and context-level indicators are used to drive personalization in EDM and LAK?

RQ3: What research gaps and future directions emerge across the two communities?

Answering these questions yields both a map and a mirror: a map of the conceptual and methodological terrain of personalization across two influential communities, and a mirror in which each community can see its strengths and blind spots. By anchoring personalization in concrete targets and signals, and by contrasting EDM and LAK along those axes, the review aims to move the conversation from whether personalization "works" in the abstract to how we can design effective, equitable, and adoptable personalization in practice.

4. METHODOLOGY

4.1 Review design and reporting framework

We conducted a structured literature review of personalization research in the LAK and EDM conference proceedings for the years 2015–2025. Our goal is to map how personalization is instantiated (RQ1), what signals are used to drive it (RQ2), and what limitations/future directions are reported (RQ3). In terms of review type, this work aligns most closely with a *scoping review* (i.e., aiming to characterize and map a body of work rather than estimate an effect size). To improve transparency and reproducibility, we report our search, screening, and selection steps in a PRISMA-compatible structure (flow counts and explicit eligibility criteria). Where PRISMA terminology is used, it is adopted as reporting guidance rather than implying a registered SLR protocol.

4.2 Information sources and search strategy (high-recall)

We searched the official proceedings and hosting digital libraries for LAK and EDM for each year in scope. To maximize recall while keeping the query auditable, we used a single high-recall lexical stem centered on `personali*`. This stem captures spelling variants and common morphological forms, including (non-exhaustively) *personalization*, *personalisation*, *personalized / personalised*, *personalizing / personalising*, and *personalizability / personalisability*. We executed the query separately for each venue-year and community. Overall, we record the authors, identifier / DOI, year, venue, title, and abstract, and exported all data to a CSV and concatenated into a raw "intake" file. Each row corresponds to one retrieved record prior to de-duplication and screening.

4.3 Eligibility criteria (inclusion/exclusion)

We predefined inclusion and exclusion criteria before screening and applied them consistently throughout.

Inclusion criteria - A record was eligible if it:

- is a paper in LAK or EDM proceedings within 2015 - 2025 (excluding workshop-only volumes if not part of the main proceedings, unless explicitly in scope);
- contains an instantiated personalization/adaptation mechanism (see operational definition below).

Exclusion criteria - A record was excluded if it:

- is not a LAK/EDM proceedings paper in scope (e.g., abstract-only items, workshops);
- mentions personalization only rhetorically (e.g., as motivation or aspiration) without an implemented adaptive mechanism.

We define personalization as an *intentional adaptation* of content, sequence/path, feedback, support, interface, or assessment to individual learners (or explicitly defined learner subgroups) using learner-specific information (data, models, or explicit rules). Mere parameter tuning at the population level, generic "one-size-fits-all" recommendations, or aspirational statements without a realized adaptive mechanism do not qualify.

4.4 Screening and selection process

Screening proceeded in two stages and was documented in a dedicated workbook sheet with validation rules.

Stage 1: about-personalization decision - We screened each unique record to determine whether it is substantively about personalization under the operational definition above. Records were labeled `Include`, `Exclude`, or `Unclear`. Unclear cases were resolved via discussion using decision notes and adjudicated conservatively (i.e., inclusion required evidence of an instantiated adaptive mechanism).

Stage 2: learning-outcomes evaluation decision - In Stage 2, we focus on outcome evidence because this review aims to synthesize support for learning impact claims, i.e., whether personalization changes what learners know or can do, rather than only whether an intervention is used, accepted, or engaging. Process characteristics (e.g., clicks, time-on-task, persistence, navigation patterns, or strategy indicators) are often meaningful as mediators or early warning signals, but they are not consistently identifiable with learning across contexts and can be driven by novelty, interface constraints, or compliance effects. Given the field's well-known risk of conflating "more activity" with "more learning", we treat process measures as learning outcomes only when a study provides an explicit validity argument that the process metric is learning-proximal in that context (e.g., validated linkage to performance/competency or a preregistered/justified surrogate endpoint). Otherwise, process measures are coded as indicators or intermediate outcomes rather than learning outcomes. For records included after Stage 1, we assessed whether the study measured effects on learning outcomes. We treated learning outcomes as changes in knowledge, skill, or performance evidenced by assessments (pre/post or delayed), mastery probabilities, grades explicitly tied to competencies, validated performance tasks, or completion when justified as competency-proximal. Engagement, usability, satisfaction, or time-on-task were not counted as learning outcomes unless explicitly validated within the study design as learning-proximal endpoints.

PRISMA-style accounting of records - To support reproducibility, we report record counts at each step:

- Records retrieved by searches in EDM and LAK: **503** (LAK: $n = 370$, EDM: $n = 133$)
- Records excluded in Stage 1 (not personalization): **269** (LAK: $n = 226$, EDM: $n = 43$)
- Records included after Stage 1: **234** (LAK: $n = 144$, EDM: $n = 90$)
- Records excluded in Stage 2 (no learning-outcome effects measured): **174** (LAK: $n = 117$, EDM: $n = 57$)
- Records included after Stage 2 (learning outcomes measured): **60** (LAK: $n = 27$, EDM: $n = 33$)

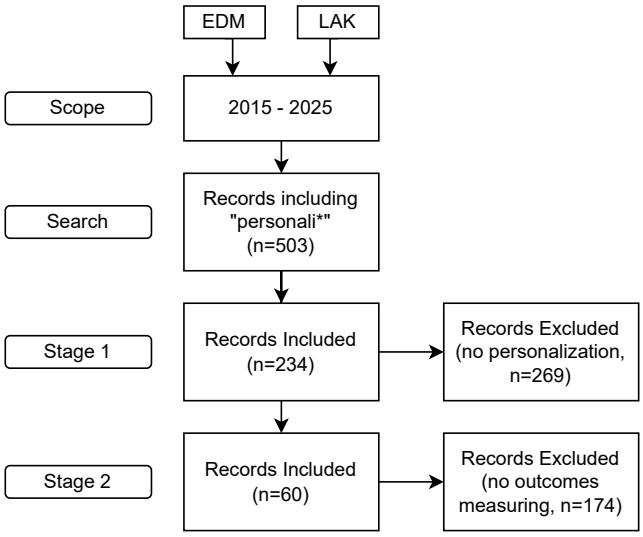

Figure 1: Inclusion and Exclusion of Records.

These counts correspond to the workbook filters and enable reconstruction of the selection process. Fig. 1 visualizes the accounting of records.

4.5 Data extraction, codebook, and coder reliability

Workbook and codebook - We maintained a multi-sheet Excel workbook as the study database. A `Dictionary` sheet defined each variable and its admissible values; `Metadata` stored bibliographic fields and provenance; `Screening` captured inclusion decisions with validation rules and inconsistency flags; and `Coding` contained analytical variables with controlled vocabularies (e.g., object of personalization, indicator families, techniques).

Coding variables - For all papers included after Stage 1, we extracted variables aligned with RQ1–RQ3. For RQ1, we coded the *object(s) of personalization* as non-exclusive categories (e.g., content, sequence/path, feedback, interface, support, assessment) and recorded domain and scale descriptors (participants and/or interaction records). For RQ2, we coded the indicators used to drive personalization (multi-select), such as knowledge-state estimates, performance history, demographics / learner profile, outcomes, behavioral traces, or social / context signals. For RQ3, we transcribed limitations and future-work statements as close paraphrases and coded them into thematic categories.

Coders and disagreement resolution - Coding was performed by **6** coders. To ensure consistency, we conducted a pilot on

30 papers to refine the codebook and decision rules. Each paper was coded by **two independent coders**. Disagreements were resolved through discussion. When ambiguous, both codings have been included. We assessed reliability on a double-coded subset of **40** papers using **Cohen's** $\kappa = .78$ for key categorical variables (Stage 1 decision, object of personalization, indicator families). Agreement was **Cohen's** $\kappa = .84$ in stage 2 and informed final refinements to the codebook prior to full coding.

4.6 Analysis

Analysis proceeded in three coordinated steps mapped to the research questions. For RQ1, we treated the object-of-personalization codes as the primary organizing axis and computed category distributions separately for EDM and LAK, yielding community-specific profiles of where personalization efforts concentrate. Because these object categories directly reflect how adaptation is instantiated, this approach supports straightforward validity checks and avoids the opacity of unsupervised topic modeling. To enrich the profiles, we examined within-category co-occurrence of indicators.

For RQ2, we compared the prevalence of indicator families across communities both overall and conditional on object category (e.g., whether knowledge-state estimates co-occur more frequently in EDM than in LAK, or whether LAK draws more heavily on learner profiles and social/context signals). For RQ3, we synthesized coded limitations and future-work themes to identify common gaps and directions, reported overall and stratified by venue and object category where informative.

In summary, this review identifies where EDM and LAK concentrate their personalization efforts (RQ1), which signals they rely on (RQ2), and which gaps are most salient for future research (RQ3).

5. RESULTS

Based on how each paper operationalizes personalization and the target goal to which personalization is optimized, we identified seven non-exclusive personalization types:

- **Learning Path (Learning Material)**: Adaptive selection and sequencing of course materials, activities, and difficulty to guide each learner's path.
- **Recommender System (Course, External Resources)**: Recommendations for courses/programs and external resources (videos, articles, apps) tailored to learners' goals and performance.
- **Dashboard**: Personalized analytics/visualizations that surface progress, risks, and suggested actions to support self-regulated learning.
- **Feedback/Support/Notifications**: Tailored hints, explanations, formative feedback, reminders, and intervention messages triggered by learner state.
- **Instruction**: Adaptation of instructional strategies and supports (e.g., tutoring policies, scaffolding, differentiated activities, teacher support allocation).
- **Scheduling**: Personalized timing and pacing - practice/test scheduling, spacing and review intervals, and ordering of assignments.
- **Collaboration/Forum**: Social personalization - peer / mentor recommendations, forum thread suggestions, group-based differentiation, and support for collaborative activities.

Papers were allocated to the personalization types as shown in the extract of Table 1. The entire table with all codings can be found at `https://doi.org/10.5281/zenodo.20023758`[79]. Six papers were excluded from type-based analyses because they could not be linked to any of the seven types ([92, 73, 51, 45, 48, 76]). Fig. 2 illustrates the absolute numbers of personalization-related papers clustered by personalization type, including all included papers (top) and the subset measuring learning outcomes (bottom). Absolute counts are shown to reflect overall research output, given the larger volume of LAK papers in stage 1, rather than emphasizing relative proportions.

5.1 RQ1: Where do EDM and LAK place their main focus, and how do those foci differ?

To test whether EDM and LAK differ in their emphasis across personalization types, we first applied Levene's tests to determine whether equal variances could be assumed. We then used independent samples t-tests when Levene's tests were non-significant and Welch tests otherwise.

Because RQ1 (and RQ2) involve comparing multiple categories, we interpret the p-values jointly rather than as independent tests. We therefore report exact p-values and effect sizes for transparency and interpret exploratory / descriptive. Given the review's descriptive / scoping aim and the non-independence of categories, we did not apply a strict family-wise correction (e.g., Bonferroni), which would be overly conservative and increase Type II error in an already power-limited setting, especially for the learning-outcomes subset ($n = 60$).

As a sensitivity check, we note that the key community differences in the full corpus (recommender systems, dashboards, and feedback / support with $p < .001$) would remain statistically significant under common false-discovery-rate control (e.g., Benjamini–Hochberg at $q = .05$), whereas marginal findings should be interpreted as exploratory and are not relied upon for central claims.

Considering all personalization-related papers ($n = 234$), Levene's tests were significant for learning path, recommender system, dashboard, and feedback/support ($p \leq .001$). Levene's tests for the remaining types were also significant ($p \leq .05$). The two-sided p-values of the Welch tests were below .001 for recommender system, dashboard, and feedback / support, indicating statistically significant differences between communities. For the remaining types, p-values were above .05, indicating no statistically significant differences at $p \leq .05$. Effect sizes were medium to large for feedback / support (Cohen's $d = -.616$), medium for recommender systems (Cohen's $d = .526$) and dashboards (Cohen's $d = -.477$), and small for learning path (Cohen's $d = .274$).

Table 1: Personalization types and indicators of LAK and EDM papers, which include personalization effects on the learning outcome (extract).

LAK	[63]	2025	-	-	-	✓	-	-	-	✓	-	-	-	-	-	✓	-	-	-	-	-

We repeated the same analysis for papers that measure personalization effects on learning outcomes ($n = 60$). Levene's tests were significant under $p \leq .05$ for learning path ($p = .002$), dashboard ($p = .012$), feedback/support ($p = .012$), instruction ($p \leq .001$), and collaboration ($p = .007$), indicating unequal variances. Neither the p-values of the two-sided Welch tests nor those of independent samples t-tests were significant under $p \leq .05$. Thus, while absolute counts suggest different emphases in the learning-outcomes subset, the subset is too small to detect statistically reliable differences.

In summary, this finding answers RQ1 and reveals that EDM and LAK papers published between 2015 and 2025 differ in terms of personalization type: LAK papers focus more prominently on feedback / support and dashboards, while EDM papers focus more often on recommender systems.

A minor difference is observed for learning-path personalization, where LAK papers occur slightly more frequently overall. For papers that also measure effects on learning outcomes, the number of included papers is too small to identify statistically significant differences. However, descriptively, 42% of EDM papers in the learning-outcomes subset focus on learning-path adaptations, while in LAK, only 22% focus on learning-path adaptations when learning outcomes are measured, although there is no remarkable difference when papers are not filtered to explicitly focus on learning outcomes.

5.2 RQ2: Which learner- and context-level indicators are used to drive personalization in EDM and LAK?

Across included papers, we identified 12 indicator categories to which each paper was linked:

- **Outcomes & Achievement**: Observable end results such as grades, test scores, pass/fail, completion, and proficiency.
- **Knowledge/Mastery State**: What the learner knows now and how it changes - KC mastery/ability estimates, probability of correctness, learning/retention.
- **Assessment & Item Properties**: Features of tasks/items - difficulty, discrimination, format, Q-matrix/skills mapping, steps/subparts.
- **Temporal Pacing & Workload**: When and how long - start/submit vs. deadlines, time-on-task, lags between sessions, workload over time.
- **Behavioral Interaction & Engagement**: Interaction traces - clicks, views, plays/pauses, navigation, resource use, attendance, dwell time.
- **Strategy, Process & Help-Seeking**: How learners work - attempt patterns, hints/scaffolds/JIT use, SRL signals (planning / monitoring), path / strategy metrics (e.g., TTS / CFA).
- **Learner Profile & Context**: Who the learner is - demographics, prior achievement / knowledge, goals / motivation, affect / anxiety, interests, availability.
- **Social & Community Signals**: Peer/community activity - posts, comments, messages, reactions, collaboration / co-authoring, centrality, participation roles.
- **Content / Curriculum**: Structure/semantics of learning materials and alignment - concepts / topics, tags, prerequisites, knowledge graphs, similarity / relevance.
- **Model / Policy Signals & Diagnostics**: System-side predictions and controls - predicted risk / performance, utilities / importance, bandit / adaptive policies, latent weights / biases, model diagnostics.
- **Work Products & Artifact Features**: Properties of learner-produced artifacts - writing (linguistic / structural features), code (tokens / AST / correctness), revisions / edits, talk / multimedia quality.
- **Records & Administrative Data**: Institutional / operational records - attendance / absences, mobility / enrollment, suspensions, assignment status, calendars / notifications, merged official logs.

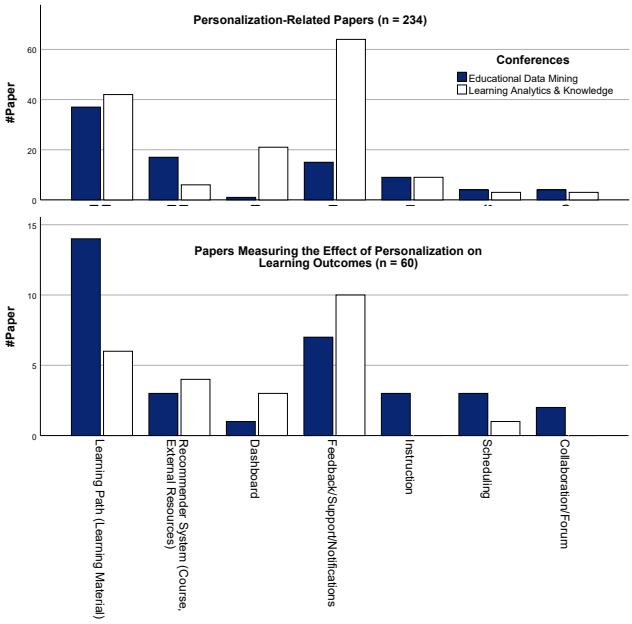

Figure 2: Personalization types in EDM and LAK papers.

To test indicator differences between EDM and LAK, we employed the same procedure as for RQ1. Levene's test was only significant for "Knowledge/Mastery State" ($p = .017$). However, across all indicators, there was no statistically significant difference in the independent samples t-tests or Welch tests when examining all personalization-related papers (Fig. 3).

Considering only papers that measured the effect of personalization on learning outcomes ($n = 60$), Levene's tests were significant for "Temporal Pacing & Engagement" only ($p \leq .001$). Again, no statistically significant differences were identified. This answers RQ2: there are no statistically reliable differences in the indicators used for personalization in EDM and LAK within the corpus, either overall or within the learning-outcomes subset.

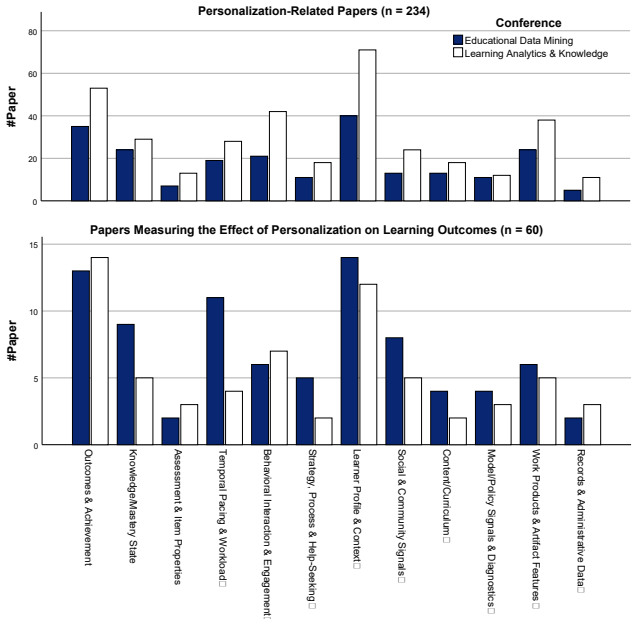

Figure 3: Personalization indicators in EDM and LAK papers.

5.3 RQ3: What research gaps and future directions emerge across the two communities?

To address RQ3, we analyzed the limitations and future-work statements reported in the included papers and synthesized them into recurrent themes. We report themes that appear across both communities, followed by community-leaning emphases.

Cross-cutting limitations (both communities) - Across EDM and LAK, reported limitations converged on threats to external validity and data quality. Many studies relied on small, context-bound samples or single-course deployments and noted limited generalizability to other settings and populations [1, 6, 27]. Cold-start and sparsity issues were frequently highlighted, especially for new learners, low-activity learners, or new content where personalization signals are weak [20, 12]. Studies also reported measurement noise, incomplete outcomes, and missing ground truth for learning constructs, which constrained robust evaluation and cross-study comparability [88, 1]. These recurring issues collectively limit confidence in transferability and reduce the feasibility of cumulative evidence building.

LAK-leaning limitations: adoption and ecological validity - Within LAK, limitations more often problematized ecological validity and adoption: platform- or course-specific interventions that do not generalize; institutional constraints on integration and data flows; instructor workload and interpretation burdens; and low voluntary engagement/compliance when interventions are deployed in authentic settings [1, 6, 15, 27, 49]. These limitations often framed personalization as a socio-technical intervention that depends on organizational fit, teacher workflow, and sustained user uptake rather than on predictive accuracy alone.

EDM-leaning limitations: model complexity and weak causal validation - Within EDM, limitations were predominantly model-centric. Papers emphasized parameter tuning difficulty, computational complexity, and overfitting risks (especially for deep or KT-style models), as well as performance degradation under distribution shift [88, 9, 25]. Another recurring theme was the gap between offline evaluation and causal impact: algorithmic improvements measured on logs or counterfactual simulations were often not validated through randomized/causal designs in authentic learning environments [38, 9].

Cross-cutting future directions (both communities) - Future-work statements commonly called for stronger evaluation and more realistic deployment contexts: online experimentation and adaptive policies embedded in courses; richer data beyond clickstream (e.g., multimodal traces); and clearer reporting standards to improve reproducibility and benchmarking [5, 41, 47, 42]. Ethical and governance themes also appeared, including fairness, privacy, and responsible use of personalization, alongside interoperability needs for cross-platform integration [33, 47, 43].

LAK-leaning future directions: human-centered orchestration and infrastructure - LAK papers more frequently emphasized moving from analytics to action through situated, human-centered interventions. Recurrent directions included teacher-in-the-loop orchestration (dashboards and workflow support), real-time adaptation in authentic contexts, interoperability and standards, and causal evaluation designs that move beyond correlational evidence [5, 11, 29, 35, 4, 15, 24, 28, 47]. Multimodal data and richer recommendation/sequencing support were also recurring motifs [41, 14, 3, 30, 46, 65].

EDM-leaning future directions: scalable policy optimization and benchmarking - EDM proposals concentrated on recommendation and curriculum sequencing, representation learning, and sequence / knowledge modeling (often extending KT) to improve personalization. Many papers also pointed to benchmarking, replicability, and robustness testing to strengthen external validity, and a growing emphasis on fairness / privacy and human-centeredness in adaptive systems [2, 23, 55, 75, 77, 9, 16, 53, 71, 82, 19, 40, 62, 69]. Overall, these results indicate that both communities articulate similar high-level needs (generalization, data quality, evaluation), but diverge in emphasis: LAK foregrounds adoption and socio-technical integration, while EDM foregrounds algorithmic generalization and policy/model validation.

6. DISCUSSION AND FUTURE WORK

The results paint a picture of two communities that are aligned in aspiration but differentiated in how personalization is *realized*, *justified*, and *validated*. This discussion interprets the three results in relation to the paper's central goal: clarifying how personalization is enacted and evaluated in EDM and LAK, and what that implies for credible progress.

6.1 Interpreting differences in personalization targets (RQ1)

The observed differences in focus can be read as a division of labor between *actionability* and *optimization*. Dashboards and feedback mechanisms are often designed around human interpretability and immediate use in learning/teaching workflows, which aligns with LAK's longstanding emphasis on making analytics actionable. Recommender systems and sequencing policies foreground algorithmic decision-making under uncertainty, fitting EDM's tradition of optimizing interventions given data and constraints. Importantly, these are not competing endpoints but complementary components of personalization at scale: optimized policies that are not interpretable or adoptable may fail in authentic settings, while actionable interfaces without validated adaptive mechanisms risk becoming advisory overlays.

A key nuance is that the learning-outcomes subset is small enough that statistical differences disappear even when descriptive differences remain. This suggests a practical constraint on the field's evidence base: personalization is frequently implemented and studied, but comparatively rarely evaluated with outcome measures in a way that supports stable comparisons across venues. Strengthening the outcome-evaluation base is therefore not merely a methodological preference; it is a prerequisite for cumulative knowledge.

6.2 Why indicators look similar across communities (RQ2)

Despite the differences in personalization *targets*, indicator usage does not differ statistically between EDM and LAK. One interpretation is that both communities draw from a shared measurement toolkit (performance, behavioral traces, context/profile, and model-derived signals), especially given overlapping platforms and datasets. Another interpretation is that the indicator taxonomy is broad enough to absorb community differences at a finer granularity: for example, both communities may use "behavioral interaction" indicators, but for different purposes (policy learning vs. teacher-facing explanation), or with different operationalizations (raw logs vs. engineered SRL constructs). In other words, the lack of indicator differences at category level should not be taken to mean that measurement practices are identical; rather, it highlights that divergence may lie in *how* signals are modeled, validated, and translated into adaptation.

This result also clarifies an opportunity: if both communities already rely on similar signal families, then shared reporting standards (feature definitions, preprocessing, missingness handling, construct validity arguments) could significantly improve reproducibility and cross-study comparability without requiring convergence on a single methodological paradigm.

6.3 From "gaps" to research programs (RQ3)

Research gaps are empirically grounded in what authors themselves repeatedly report. The discussion here focuses on what those recurring themes imply for a forward research program.

First, the cross-cutting limitations (context-bound samples, sparsity/cold-start, noisy and incomplete outcomes) point to a deeper structural issue: personalization research often advances through *bespoke* deployments and datasets, which hinders external validity. This suggests that progress depends on infrastructure-level changes: shared benchmarks where appropriate, multi-site studies, and more consistent definitions of what constitutes "personalization" and "learning outcomes" across contexts. Without these, even strong individual studies remain difficult to synthesize.

Second, the community-leaning emphases are complementary and could be integrated into more powerful evaluation and design patterns. LAK's adoption/ecological-validity concerns indicate that personalization should be evaluated as a socio-technical intervention embedded in workflows, constraints, and incentives. EDM's model-centric concerns indicate that personalization should be stress-tested for robustness, generalization, and policy validity beyond offline gains. A combined program would therefore evaluate personalization *end-to-end*: from signal quality and model robustness, through interface and orchestration, to causal impact on learning.

Third, the repeated call for stronger causal validation suggests that "better models" and "better dashboards" are insufficient if research designs cannot distinguish personalization effects from confounds. Pragmatic experimentation (e.g., online A/B tests, stepped-wedge rollouts, teacher-mediated randomization) and careful measurement design (validated outcomes, delayed post-tests, or competency-proximal assessments) are needed to turn personalization into reliable practice. The rarity of learning-outcomes evaluations in the corpus implies a field-level bottleneck: many studies stop at plausibility or engagement metrics, leaving learning impact under-evidenced.

Finally, ethics and governance themes (fairness, privacy, explainability) appear as an emergent but not yet uniformly operationalized agenda. A practical implication is that these considerations should be connected to the same objects / indicators / techniques framework used in this review. For example, fairness risks differ between a course recommender and a mastery-based sequencer; privacy risks differ between administrative records and multimodal sensing; explainability requirements differ between teacher-facing dashboards and learner-facing feedback. Treating ethics as design- and context-dependent, rather than as a generic checklist, is likely to make it more actionable across both communities.

6.4 Implications for cross-fertilization

Taken together, the results suggest a productive synthesis: EDM contributes scalable modeling and policy optimization methods, while LAK contributes human-centered orchestration, interpretability, and deployment realism. Cross-fertilization could be accelerated by (i) adopting shared reporting standards for personalization objects, signals, and evaluation designs; (ii) building evaluation pipelines that explicitly connect offline metrics to online impact; and (iii) designing systems where policy learning and human oversight are co-designed rather than bolted together. Such work would directly address the dominant limitations reported in both communities while preserving their strengths.

7. LIMITATIONS

This review offers a structured, comparative synthesis of personalization research in EDM and LAK between 2015 and 2025, but several limitations constrain the interpretation and generalization of the findings. The corpus was intentionally limited to papers published in the LAK and EDM conference proceedings to support direct comparisons between two influential communities. While this restriction improves internal coherence, it also narrows coverage by excluding relevant contributions published in journals and adjacent venues where personalization is frequently studied and where longer-term deployments, multi-institution evaluations, and theory-building work are often reported. Consequently, the patterns identified here should be understood as reflecting the proceedings-centered discourse of these two conference ecosystems rather than the full landscape of educational personalization research.

Our retrieval strategy employed a single high-recall lexical stem (`personali*`) to ensure auditability and capture common spelling and morphological variants. Although this choice strengthens reproducibility, it can lead to both false negatives and false positives. Relevant work may be missed when personalization is instantiated under alternative terminology (e.g., adaptive tutoring, individualized sequencing, targeted intervention, mastery-based progression, or recommendation framed without explicit "personalization" language), and records may be retrieved where personalization is invoked primarily as motivation rather than as an implemented mechanism. Accordingly, the resulting corpus depends not only on the search term but also on subsequent screening decisions.

The review further relies on an operational definition of personalization as system-driven, individual-level adaptation (or explicitly defined subgroups) based on learner-specific information. This definition provides conceptual clarity, but it may exclude studies in which personalization is enacted primarily through human mediation (e.g., instructor decision-making supported by analytics) or where personalization is realized as infrastructure, workflow integration, or institutional practice rather than as an explicit adaptive mechanism in software. Borderline cases are inevitable in a heterogeneous literature, and although adjudication procedures were used, some degree of classification error remains possible. Similarly, the second-stage distinction between studies that measure learning outcomes and those that report engagement, usability, or satisfaction requires interpretive judgment because papers do not always report outcomes with sufficient construct validity arguments or consistent operationalization. Proxies such as completion or time-on-task may be treated as learning-proximal in some contexts but not in others, and ambiguity in reporting can affect categorization.

The coding scheme necessarily abstracts across substantial within-category heterogeneity. Targets of personalization and indicator families were treated as non-exclusive categories, reflecting the fact that many systems combine mechanisms and signals. However, this design complicates inference because category frequencies do not correspond to mutually exclusive partitions, and coarse taxonomies can mask differences in how signals are operationalized and validated. For example, "behavioral interaction" may denote raw clickstream counts, engineered self-regulated learning constructs, or multimodal engagement indicators; "knowledge/mastery state" may arise from classical cognitive models, deep knowledge tracing variants, or hybrid approaches. As a result, small differences at the category level should not be interpreted as equivalence in measurement practice or modeling choices.

Quantitative comparisons are based on counts of papers coded into categories and employ standard significance tests. This approach treats papers as independent observations and does not explicitly account for dependencies such as recurring authorship, shared datasets, or coordinated research programs that may cluster publication patterns. Moreover, the subset of included studies that evaluate learning outcomes is comparatively small, limiting statistical power to detect stable differences between communities in that subset. Non-significant findings in the learning-outcomes analyses should therefore be interpreted cautiously as insufficient evidence for differences rather than evidence of no differences.

Finally, this work is not a meta-analysis and does not estimate pooled effect sizes. The included studies vary widely in context, intervention types, outcome measures, duration, and evaluation designs, ranging from offline analyses and observational studies to quasi-experiments and randomized evaluations. This heterogeneity limits the appropriateness of aggregating effects and complicates causal interpretation, particularly when reports omit information needed to assess internal validity (e.g., randomization fidelity, attrition, contamination, or multiple testing control). In addition, the synthesis of limitations and future-work statements depends on what authors choose to report and may be affected by reporting bias, page constraints, and selective emphasis, potentially underrepresenting negative results, failed deployments, or governance constraints such as privacy and fairness trade-offs. Taken together, these considerations indicate that the present review is best read as a transparent, reproducible map of how personalization is operationalized and evaluated in LAK and EDM proceedings during 2015–2025, rather than as an exhaustive census of all personalization research or a definitive causal estimate of personalization effectiveness.

8. CONCLUSION

EDM and LAK both pursue personalization, but they do so through different lenses, as this literature review has examined. This review compared how EDM and LAK operationalize personalization (2015 – 2025) by what is adapted, the indicators that guide personalization, and how effects are evaluated. We find distinct foci - LAK leans toward feedback and dashboards, EDM toward recommender/sequencing, but no systematic differences in indicator usage. Shared limitations include context-bound samples, data sparsity, and measurement noise; LAK stresses adoption/ecological validity, while EDM emphasizes model complexity and weak causal validation. Progress hinges on combining EDM's policy/model advances with LAK's human-centered orchestration, supported by practice-grounded trials, cross-platform benchmarks, and clear reporting of objects, indicators, and evaluation designs.

ABSTRACT

Learning analytics (LA) and educational data mining offer powerful ways to study self-regulated learning (SRL), but privacy constraints often restrict access to authentic learner data, limiting reproducibility and collaboration. Synthetic data generation (SDG) provides a promising approach by preserving statistical properties of real data while mitigating privacy risks. This study evaluates synthetic SRL datasets along three dimensions: their resemblance to real data, their utility for predicting student success, and their capacity to reproduce prior explainable AI (XAI) findings. Results show that BayesNet-based SDG most effectively approximated real data and enabled predictive models that in some cases outperformed those trained on authentic data. Synthetic datasets also replicated XAI stability metrics from prior work, though contextual effects such as those linked to COVID-19 remained difficult to capture. Grounded in SRL theory, this study demonstrates both the promise and limitations of SDGs and contributes a publicly available multidimensional dataset for open LA research.

Keywords

Synthetic data, explainable AI, learning analytics

1. INTRODUCTION

Advancements in data collection and processing within the educational domain have given rise to the field of learning analytics (LA), which aims to optimize learning processes and environments in a data-driven manner [39]. Self-regulated learning (SRL), which has been shown to be important for student success [53, 54], can be studied by processing the data traces left by students interacting and engaging with online environments [49]. The potential of LA data to capture SRL is well-recognized [48]. Additionally, Educational Data Mining (EDM) can help to operationalize SRL constructs, to investigate the relationships between these constructs, to model and understand student learning trajectories, and to clarify how far we can trust conclusions and findings [49]. LA trace data has been shown to be most informative for predicting student success when higher level study indicators are generated from the highly granular trace data [17]. Dashboards and other LA tools that provide support for SRL aspects such as goal setting, monitoring, and self-reflection have been shown capable of positively influencing learning motivation and engagement, on condition that tools explicitly link their functionalities to SRL theories and constructs [55], and are grounded in educational theories [30, 46]. Extracting meaningful SRL indicators from trace data using EDM is an important prerequisite for providing effective LA tool support.

The use of actual, real-world trace data to support LA and evaluate SRL effectiveness is hindered by ethical and privacy concerns [43]. Access to real learning data is often restricted due to privacy regulations such as the GDPR in Europe, as well as institutional policies on processing student data – where data collection primarily serves the organization and administration of education. These restrictions complicate open science and collaborative research. One promising solution is the generation and use of synthetic data, which is a class of techniques that preserve the statistical properties of the original datasets while reducing the risks of information disclosure, re-identification or reconstruction [4]. This promise is amplified by recent advances in GenAI techniques capable of generating structured tabular datasets [18]. The synthetic data generation approach is especially valuable in large educational information systems composed of multiple services owned by different stakeholders, where data sharing is inherently challenging. By enabling safer data exchange, synthetic data can facilitate faster system development and testing, promote collaboration, and support broader adoption of LA [4].

In this paper, we examine the extent to which artificially generated data on learners' self-regulation (1) resembles real data, (2) can be leveraged to predict student success, and (3) enables the replication of prior studies on explainable AI (XAI) in LA. Our primary contribution is an in-depth comparative evaluation of the potential of synthetic datasets within the broader LA research domain, along with an analysis of their use in the context of XAI stability. In addition, we provide a synthetic dataset that addresses the scarcity of publicly available LA data. To support the link with SRL, we focus on a dataset constituted of SRL indicators, next to outcome data. This dataset is multi-dimensional, spanning multiple courses and academic years, and thus supports out-of-sample validation across both contexts and time.

This paper is organized as follows. Section 2 discusses related work, identifies research gaps and states the research questions. Section 3 details the study's methodology, including descriptions of the data and synthetic data generators, as well as the analysis setup. Section 4 reports the findings and Section 5 provides a broader discussion of the results, including the limitations and directions for future work. Finally, Section 6 summarizes the main contributions.

2. RELATED WORK

2.1 Synthetic Data Generation in LA

Privacy and confidentiality concerns have driven the adoption of synthetic data generators (SDGs). These tools are capable of learning the characteristics of real datasets to produce synthetic data with similar statistical properties [51]. Several publicly available SDG libraries exist, including Synthcity [35] and the Synthetic Data Vault (SDV) [33].

Statistical techniques such as Markov models or Bayesian networks (BayesNet) are widely used for synthetic data generation in education. Flanagan et al. [11] investigated the effectiveness of using synthetic educational data for real-world scenarios involving data sharing with third parties. The synthetic data was generated using a first-order Markov model trained on real interaction data from a digital material reading system, where learner actions were modeled as states and transition probabilities were learned from the original dataset. To evaluate the quality of the synthetic data, models were trained on it to predict academic achievement and then tested on real, private data. Several of these models showed significantly lower performance when applied to the non-synthetic datasets, indicating limitations in the utility of the synthetic data. On the other hand, the experiment of Dorodchi et al. [9] generated synthetic educational data using Bayesian networks and the models trained on synthetic data performed similarly to those trained on real data in benchmark tasks, suggesting synthetic data can be a viable alternative for algorithm development in LA.

In many machine learning (ML) studies, statistical methods are frequently benchmarked against more complex deep learning models (e.g., [14]), and SDG is no exception. Zhan et al. [51] evaluated four SDG techniques – GaussianCopula, CTGAN, CopulaGAN, and TVAE – for their ability to generate high-quality synthetic student data. Their evaluation followed a two-step process: (1) comparing the distributional similarity between synthetic and original datasets; and (2) assessing the utility of the synthetic data in LA tasks such as regression and classification. The results indicated that GaussianCopula and TVAE performed best, producing synthetic data that both closely mirrored the original distributions and enabled strong performance on downstream tasks. Expanding on this, Liu et al. [25] conducted a comparative analysis of SDGs in LA – including Gaussian Multivariate (GM), Gaussian Copula, and CTGAN – using metrics for similarity, utility, and privacy. While GM performed well in terms of utility, it fell short in privacy protection: the close resemblance between GM-generated synthetic data and the real data increases the risk of exposing sensitive information. In contrast, Gaussian Copula offered the most balanced performance across all three dimensions, making it the preferred choice for LA tasks.

The emergence of large language models (LLMs) has spurred their adoption in the domain of synthetic data generation. In addition to the widely used CTGAN model, Khalil et al. [18] employed three different LLMs to generate synthetic tabular data. The resulting datasets exhibited strong alignment with real-world data, particularly in terms of statistical similarity. Their findings showed that CTGAN achieved performance comparable to that of the LLM-based approaches, with both CTGAN and DialoGPT emerging as the top performers overall.

Liu et al. [24] investigated the trade-off between privacy and fairness in synthetic data generation, evaluating both GAN-based models and LLMs using standard ML algorithms as well as fairness-aware methods. In LA, privacy concerns center on obtaining learners' consent for data collection and preventing harm from data sharing, while fairness focuses on avoiding the reinforcement of existing societal biases against minority groups in LA solutions. Their study found that the DECAF model achieved the best overall balance between privacy and fairness, albeit at the cost of the lowest utility performance. For use cases where privacy is the primary concern, ADSGAN was identified as the most suitable option. Table 1 summarizes the abovementioned studies on investigating the performance reported for existing SDGs.

2.2 Stability Analysis in Learning Analytics

One of the key downstream tasks in LA is predicting student success using ML models trained on learning indicators derived from detailed study activity data, in alignment with SRL theory [17]. The insights generated by these models can support feedback provision, such as personalized study advice and timely interventions. However, real-time study data is not always accessible due to privacy regulations (e.g., GDPR), making models trained on historical data the default choice for many LA practitioners. Consequently, the usefulness of these models depends on their stability across academic years and their ability to adapt to changing contexts [31].

Tempelaar et al. [41] investigated the stability and sensitivity of LA prediction models across different student cohorts and instructional designs by using linear regression models. They find that models are stable when the instructional design remains unchanged, maintaining similar predictors and accuracy. However, when the course design changes, the models show sensitivity, hence affecting model stability. Saqr et al. [38] perform a single-paper meta-analysis

Table 1: Summary overview of the most prevalent related work.

Source	Type of techniques	Data source	Purpose	Performance effects
[11]	Statistical: Markov model	Digital material reading system	Data sharing	↓
[9]	Statistical: BayesNet	Demographics, academic performance	Open science, privacy	∼

∼ Performance is on par with real data;
↓ Performance is worse than with real data

(using correlation analysis for each individual analysis) to identify which commonly used LA indicators reliably generalize across course runs, reporting total activity and forum participation as the most consistently portable predictors across similar course contexts.

Tiukhova et al. [44] extended prior work by evaluating the stability of LA models over time and across student cohorts, employing both statistical and ML techniques alongside XAI methods. By integrating XAI, they introduced an important explainability dimension into model stability analysis. XAI encompasses a variety of approaches that make AI models "more intelligible to humans by providing explanations" [15]. In educational settings, explainable AI (XAI-ED) has been conceptualized as a structured framework that addresses six interrelated dimensions – stakeholders, benefits, explanation methods, model types, human-centered interface design, and explanation-specific pitfalls – in order to meet the unique needs of educational contexts [19].

Building on this foundation, Tiukhova et al. [44] combined concept and prediction drift analysis with explainability as a diagnostic tool. They demonstrated how feature-importance rankings generated by SHAP [29] can be used to assess whether model explanations remain consistent across cohorts. They show that explainability can enrich stability analysis by complementing traditional techniques and uncovering new insights: SHAP not only clarified model predictions but also functioned as a diagnostic tool for evaluating global model stability across contexts. The authors conclude that LA models should be updated, as only general engagement metrics consistently remain reliable [44].

2.3 Research gap and research questions

Evaluating reproducibility is a key requirement for ensuring generalizable outcomes in both LA and SRL research. However, it has not been systematically explored yet in the context of SDGs. This paper addresses this gap by specifically examining the reproducibility of existing LA research findings on model stability across cohorts and over time, i.e., whether models and their explanations remain consistent across time and cohorts [44] when synthetic data is used for these models. Crucially, the artificially generated data is based on a dataset containing meaningful SRL indicators to ensure that its educational relevance and interpretability are preserved. In addition, it is essential to compare the reproducibility-oriented utility of SDGs with more conventional measures – statistical resemblance and predictive performance – to determine whether commonly used evaluation criteria truly reflect the capacity of synthetic data to support valid and transferable LA research conclusions. The research therefore first assesses the quality of the synthetic data along the state of the art dimensions of statistical resemblance (RQ1) and prediction performance (RQ2). It then advances the state of the art by investigating the reproducability of the stability analysis (RQ3) and verifying the alignment to the results of RQ1 and RQ2. The RQs are therefore as follows:

RQ1 Statistical resemblance To what extent does synthetic data resemble real data in terms of distributional similarity, and which SDG algorithms produce the most realistic distributions?

RQ2 Prediction utility How effectively can synthetic data be used for student success prediction, and which SDG algorithms yield a dataset that can be used to train the models with the highest prediction performance when applied to the real data?

RQ3 Replication utility To what extent can synthetic data be used to replicate existing research going beyond predictions – specifically, the stability analysis conducted by Tiukhova et al. [44] – and which SDG algorithms produce a dataset allowing for the highest degree of reproducibility of the stability analysis?

3. METHODOLOGY

We first discuss data collection and feature engineering activities, after which we detail the selected SDGs for this study. Then, we elaborate on the main methodology to assess (i) statistical resemblance, (ii) prediction utility, and (iii) replication utility to address the respective research questions (Figure 1).

3.1 Data and Feature Engineering

In the light of RQ3, it was decided to base the research on [44] and the original data was obtained from the authors.

It represents online study behavior and academic achievement for two compulsory courses (Accountancy and Global Economics) of first-year bachelor students from KU Leuven, for three consecutive academic years (AY): 2018-2019, 2019-2020, and 2020-2021. The Accountancy course was offered in the first semester while the Global Economics course is delivered during the second semester. When mapping this to the external contexts of education during the aforementioned AYs, we can see that the Accountancy course was affected by COVID-19 in AY 2020-2021, while the Global Economics course was affected by COVID-19 during both 2019-2020 and 2020-2021. In [26], this external change was found to have a significant effect on studying patterns.

The raw data represents student's activity on the course's LMS page, including granular interactions with course material and contribution and consumption of the discussion forum. To ground the analysis in the educational sciences and SRL theory in particular, the granular data is used to construct representative SRL indicators that represent motivated learning choice along different dimensions [17].

To mitigate an excessive loss of significance, the SDG was based on the featurized dataset developed in [44] instead of the raw data. The features selected by [44] build on prior work by [45], [17], and [40]. Specifically, [17] models study behavior along two dimensions: level of activity and study regularity. For each dimension, both overall patterns and learning-action–specific patterns are captured, yielding four feature categories: overall level of activity (OLA), learning-action–specific level of activity (LALA), overall regularity of study (ORS), and learning-action–specific regularity of study (LARS). For the action-specific features, four types of learning activities are further distinguished: forum contribution, forum consumption, access to learning materials, and access to the main course page. This feature set was further enriched with features inspired by financial consumption patterns that measure exploration, exploitation, and plasticity of human consumption [40]. Feature selection was performed using correlation analysis, resulting in a final set of 16 features (no categorical features) used in the analysis [44]. Study success is operationalized using the summative grade from the first exam attempt (scored on a 0–20 scale, with a passing threshold of 10). These grades are subsequently transformed into a binary pass/fail outcome variable [44]. More details on feature engineering process and dataset characteristics can be found in [44] and [45].

3.2 Synthetic Data Generators

We use three well-established SDG models (see Table 1), each representing a distinct approach: a statistics-based BayesNet, an autoencoder-based model (TVAE), and an adversarial learning-based model (CTGAN) (the generated datasets can be found on Zenodo [42]). We exclude LLM-based models due to their similar performance to other deep learning methods, allowing us to avoid the additional computational cost associated with LLMs (see Table 1). These SDGs are used to generate single-table synthetic data from the original dataset after applying feature engineering, an approach widely used in the literature [51, 25]. The feature engineering process follows the methodology described in [44], resulting in 16 predictors that capture student SRL behaviors, along with one target binary variable indicating whether the student passed the first exam attempt.

The Conditional Tabular Generative Adversarial Network (**CTGAN**) model uses the principle of the original GAN model [13] when generating synthetic data samples while simultaneously addressing its main shortcomings, i.e., working with mixed data types, non-Gaussian and multimodal distributions and highly imbalanced categorical columns [50]. Like the original GAN, CTGAN has a generator that learns to produce synthetic tabular data imitating real data and a discriminator that learns to distinguish between real and synthetic samples. We implement CTGAN using the *ctgan* plugin from the Synthcity library [35] and its default hyperparameters (max. 1000 encoder iterations; 3 hidden layers in both encoder and decoder, each with 500 hidden units; leaky ReLU activation function in encoder, with a dropout rate of 0.1; leaky ReLU activation function in decoder, with no dropout; learning rate of 0.001, L2 regularization of 0.00001; batch size of 200; early stopping after 100 epochs if no improvement during 5 epochs; gradient clipping of 1).

The Table Variational Autoencoder (**TVAE**) [50] is an adaptation of a variational autoencoder [20] for mixed-type tabular data generation. It consists of an encoder that maps data to a latent distribution and a decoder that can reconstruct the input by sampling from this learned latent distribution. We implement TVAE using the *tvae* plugin from the Synthcity library [35] and its default hyperparameters (max. 2000 generator iterations; 2 hidden layers in both generator and descriminator, each with 500 hidden units; ReLu activation function in generator, dropout rate of 0.1; beta tuple in the generator optimizer of (0.5, 0.999); leaky ReLU activation function in discriminator, dropout rate of 0.1; 1 iteration of discriminator per generator iteration; beta tuple in the discriminator optimizer of (0.5, 0.999); learning rate of 0.001 and L2 regularization of 0.001; batch size of 200; gradient clipping of 1 and gradient penalty of 10; early stopping after 100 epochs if no improvement during 5 epochs).

A Bayesian network (**BayesNet**) is capable of capturing the correlation structure between attributes, making it possible to further sample data from the learned distribution. This structure is represented via a directed acyclic graph (DAG), used to sample synthetic data points [3]. We implement synthetic data generation with BayesNet using the *bayesian_network* plugin from the Synthcity [35] and its default hyperparameters (max. 1000 learning iterations, tree-structured BayesNet; K2 score as a Bayesian scoring metric; up to 4 parent nodes for each node).

3.3 Statistical resemblance (RQ1)

To assess the statistical resemblance of the synthetic datasets, we employed the Kolmogorov–Smirnov (K-S) test [21] for the independent variables and the chi-squared test [34] for the dependent variable (Figure 1).To evaluate multivariate fidelity, we use the SynthEval tool [23] to compute (1) the differences between mixed correlation matrices, which quantifies the preservation of pairwise linear dependencies, and (2) the differences between mutual information matrices, which capture the extent to which general (including non-linear) statistical dependencies between variables are preserved.

The K-S test is a non-parametric statistical test used to compare the empirical distribution functions of two samples. It quantifies the maximum absolute difference between their cumulative distribution functions and tests the null hypothesis that both samples are drawn from the same distribution [21]. The main motivation for using the K-S test lies in its widespread adoption in the literature [25], as it is non-parametric and sensitive to differences in both location and shape – making it a natural fit for LA settings where concept drift and cohort changes are common. Recent LA work explicitly uses K-S to monitor year-over-year shifts in student-behavior features [44]. Beyond LA, K-S is one of the main metrics in the tabular data evaluation framework *SynthEval* of Lautrup et al. [23], which presents a robust implementation and reports summary diagnostics such as the average K-S distance and the fraction of attributes flagged as significantly different. K-S tests are also commonly listed among fidelity measures in recent various evaluations, reinforcing its status as a standard similarity test when judging whether synthetic data preserves key marginal distributions [28, 27]. We apply the K-S test feature-wise to compare the synthetic SRL features to their corresponding real features, allowing us to detect whether any statistically significant distributional drift occurred between them.

The chi-squared test is a statistical method for comparing categorical data across two or more groups [34]. It is commonly used in data drift detection for categorical features, where the null hypothesis states that the feature distribution in the current dataset matches that of the reference dataset. In this study, we use the test to assess differences in the distribution of the target variable (the binary pass/fail feature) between the synthetic and real datasets.

The mixed correlation matrix (MCM) difference is computed as the Frobenius norm of the difference between correlation matrices derived from the real and synthetic data. Specifically, Pearson correlation is used for numerical–numerical pairs, Cramér's V for categorical–categorical pairs, and the correlation ratio η for categorical–numerical pairs [52]. Lower values indicate greater similarity in pairwise linear and association structure. The mutual information matrix (MIM) difference is computed analogously as the Frobenius norm of the difference between pairwise normalized mutual information (NMI) matrices. Here, NMI quantifies general (including non-linear) dependencies between variables, with lower values indicating closer agreement between real and synthetic data.

3.4 Prediction utility (RQ2)

For prediction utility analysis, we used the "train on synthetic, test on real dataset" workflow, i.e., we trained classifiers on synthetic datasets and evaluated their performance on a held-out portion (30%) of the corresponding real dataset (Figure 1). This was compared against a baseline where the models were trained on 70% of the real data and tested on the same 30% real data holdout. We selected three classification algorithms that vary in complexity including a linear model – Logistic Regression (LogReg) [32], a linear probabilistic model – Gaussian Naive Bayes (GaussNB) [36], and a tree-based ensemble model – XGBoost [6]. These models are also widely used in the LA literature for student success prediction [1, 7]. Each model underwent hyperparameter tuning via grid search with 5-fold stratified cross-validation, using balanced accuracy as the evaluation metric. This metric was selected because many of the datasets – both real and synthetic – exhibit varying degrees of class imbalance between pass and fail outcomes (see Appendix A, Table 9). Balanced accuracy offers a more reliable measure of performance in such settings, as it reflects the ability to correctly classify both classes irrespective of their prevalence. The Wilcoxon signed-rank test, which assumes as its null hypothesis that two paired samples come from the same distribution [47], is used to assess whether the performance of models trained on synthetic data differs from that of models trained on real data. The entire pipeline is illustrated in Figure 1, which outlines the full evaluation process from data preparation to model training and evaluation.

3.5 Replication utility (RQ3)

To demonstrate the value of synthetic data for replication analysis, we replicate the model agreement evaluation study conducted in [44]. In this paper, we define replication (or reproducibility) utility as the extent to which findings concerning a model's stability across study cohorts remain consistent when synthetic data is used. In [44], model stability is examined in the context of using model-derived insights to support educational advising. For black-box models, these insights are obtained through XAI techniques, which enable educators to interpret model outputs and incorporate them into advising practices. Owing to ethical and privacy constraints, such advice is typically based on data from previous course runs. Within this setting, stability is characterized as the consistency of the model's "reasoning", operationalized as the consistency of global feature importance as revealed by the explainability method, specifically Kernel SHAP [29]. In student success prediction, these features correspond to students' SRL capabilities, and the relative importance of each SRL dimension is critical for informing effective interventions. Accordingly in [44], the degree to which a feature's importance remains stable across successive course runs constitutes the core notion of stability.

Specifically, we use synthetic data to train and evaluate a range of model configurations that vary both in the choice of algorithm and the data used for training and testing. Eight ML algorithms are considered: Naïve Bayes (NB) [37], Support Vector Machine (SVM) [16], Multi-Layer Perceptron (MLP) [37], Logistic Regression (LR) [32], K-Nearest Neighbors (KNN) [8], Random Forest (RF) [5], XGBoost (XGB) [12], and TabNet (TAB) [2] – see [44] for further details.

Model evaluation is conducted across four different pipelines, which differ primarily in the AY data used for training and testing the model with optimal hyperparameters (as determined by cross-validation): (1) the optimal model of AY T-1 data applied on AY T-1 test data, (2) the optimal model of AY T-1 applied on AY T test data, (3) the optimal model of AY T-1 retrained on AY T data applied on AY T test data and (4) the optimal model of AY T applied on AY T test data. For each pipeline, feature importance rankings are generated using the Kernel SHAP algorithm [29].

Kernel SHAP is an additive feature attribution method that decomposes a model's prediction into the contributions of each input feature. For every data sample, it assigns a score

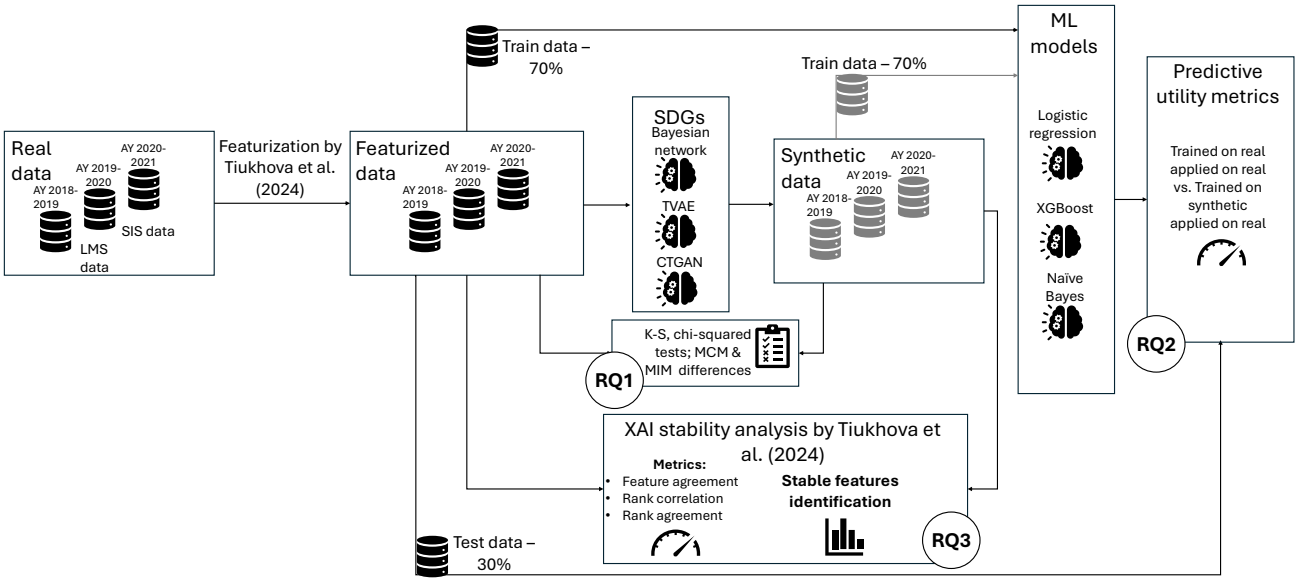

Figure 1: Analysis Pipeline

to each feature representing its importance in generating the prediction. By averaging the absolute SHAP values across all samples, one can estimate global feature importance and produce feature rankings. These rankings are then used to compute stability metrics widely used for investigating a general disagreement problem in the XAI domain [22]: feature agreement, rank agreement, and rank correlation. Feature agreement measures the overlap in the top-k important features between models, while rank agreement captures both the shared top-k features and their relative positions in the rankings. Rank correlation assesses the overall consistency in feature importance orderings across models. For detailed metric definitions and formulas, refer to [44].

In this study, we compute these stability metrics using synthetic data. Additionally, we replicate the stable feature identification analysis by determining which features consistently appear among the top eight across all four model configurations. Finally, we compare our results with those reported in [44] to assess whether the key findings hold when using synthetic data.

4. RESULTS

RQ1 - Statistical resemblance. Table 2 displays the K-S test results (p-values) evaluating how well the feature distributions in the synthetic datasets match those of the original data. Values below 0.05 indicate statistically significant drift between real and synthetic data distributions and are printed in bold in the tables. Based on this criterion, TVAE performs the worst, with the highest number of bolded entries across academic years and courses, suggesting substantial distributional drift. CTGAN shows a moderate level of fidelity, with fewer instances of drift than TVAE, though still not consistently preserving all features. Notably, the BayesNet outperforms both, demonstrating stronger distributional resemblance across most features, especially in more recent years, with comparatively few cases of drift. However, it is important to highlight that the binary Pass/Fail outcome consistently exhibits drift across all years and both subjects, with Bayesian Network models showing this most prominently. Notably, the imbalance ratio in the synthetic data does not systematically deviate in a single direction, but instead varies across settings, sometimes overestimating and sometimes underestimating the minority class (Appendix A, Table 9). This indicates that the model does not reliably preserve the class prior, but rather exhibits high variance in its estimation under class imbalance. The effect is exacerbated by the sparse representation of the minority class, which leads to unstable conditional probability estimates.

Table 3 shows that across both datasets and all academic years, BayesNet consistently achieves the lowest mixed correlation and mutual information matrix differences, indicating superior preservation of both linear and general dependency structures. CTGAN exhibits moderate performance, while TVAE consistently shows the largest deviations, suggesting weaker fidelity in capturing multivariate relationships. The consistency of these results across metrics and cohorts indicates that the observed performance differences are systematic rather than dataset-specific.

RQ2 - Prediction utility. Table 4 reports the differences in balanced accuracy scores on the test set for three algorithms (LogReg, GaussNB, and XGBoost) trained on real data and on synthetic data generated by BayesNet, TVAE, and CTGAN, across multiple courses and years. Negative values indicate that models trained on synthetic data outperformed their real-data counterparts, while positive values indicate the opposite. BayesNet produced 12 negative values, TVAE 8, and CTGAN 9. On average, BayesNet achieved the strongest prediction utility, with a mean balanced accuracy difference of –0.0287, reflecting superior generalization to the real-data holdout. CTGAN followed closely

Table 2: Drift detection results (p-values) for synthetic data generated with BayesNet, CTGAN, and TVAE. Chi-squared test was used for the binary Pass/Fail outcome and the K–S test for numerical features.

(–0.0051), while TVAE was the only method with a positive mean difference (+0.0186), indicating weaker performance relative to the real-data baseline. Notably, this pattern suggests that higher statistical fidelity – as measured by the K-S test, mixed correlation matrix difference and pairwise mutual information difference – correlates with stronger generalization in this setting.

To assess the statistical significance of these differences, we applied the two-sided Wilcoxon signed-rank test to compare the distributions of metric values from models trained on real versus synthetic data. Results showed that BayesNet's scores differed significantly from those based on real data ($p = 0.027$), whereas neither TVAE ($p = 0.130$) nor CTGAN ($p = 0.899$) reached significance. To further test BayesNet's potential advantage, we conducted a one-sided Wilcoxon test with the alternative hypothesis H_1 : BayesNet > Real, which was also significant ($p = 0.013$). Taken together, these findings indicate that models trained on BayesNet-generated synthetic data can not only match, but in some cases surpass, the performance of models trained on real data.

RQ3 - Replication utility. Table 5 displays the agreement metrics calculated based on the SHAP global rankings built for the models trained and applied on synthetic data generated with BayesNet, CTGAN and TVAE models, respectively. Darker colors in the tables represent higher agreement. What can be seen immediately is that the strictness of the metrics (metric strictness refers to the degree to which a stability metric imposes additional conditions on agreement, with stricter metrics requiring not only feature overlap but also stronger alignment in ranking or relative ordering) that was demonstrated in the original paper [44] (as shown in Table 6) is preserved: rank agreement stays the strictest metric. Moreover, the pattern of decreasing agreement of updated models is preserved too: we see the highest agreement for the cases where the model is applied as-is, while

the lowest agreement is achieved once the model's hyperparameters were updated and the model itself was retrained. Another observation that we make is the fact that the Naive Bayes model demonstrated the highest agreement, similarly to what was reported in [44].

Another finding of [44] concerns the differences in agreement metrics calculated in different external contexts. Table 7 illustrates this fact by presenting the differences in the stability metrics between the comparisons made for the AYs that share the same external context (COVID-19 vs. COVID-19 or non-COVID-19 vs. non-COVID-19), and the comparisons that do not share the same context (non-COVID-19 vs. COVID-19). In other words, for the Accountancy course offered in the first semester, the difference is calculated by subtracting the metrics of the comparison AY 2018–2019 vs. AY 2019–2020 (non-COVID-19 vs. non-COVID-19) from those of the comparison AY 2019–2020 vs. AY 2020–2021 (non-COVID-19 vs. COVID-19). For the Global Economics course offered in the second semester, the difference is calculated by substracting the metrics of the comparison AY 2019-2020 vs. AY 2020-2021 (COVID-19 vs. COVID-19) from those of the comparison AY 2018-2019 vs. AY 2019-2020 (non-COVID-19 vs. COVID-19).

These differences were found to be positive in [44], as a shared context was expected to result in higher agreement (bold values in Table 7). However, when examining stability across different academic years calculated using the data generated with SDGs, we do not observe the same pattern. Specifically, the stability metrics are not consistently higher for comparisons involving academic years with a shared external context (see red-highlighted values in Table 7).

Such behavior can be explained by the simplifying assumptions underlying the SDGs. In particular, SDGs based on probabilistic graphical models capture dependencies only among explicitly modeled variables (learning behavior in this paper); therefore, if the external context (e.g., a COVID-19 indicator) is not explicitly encoded as a conditioning variable, its indirect or latent influence on agreement patterns cannot be reproduced in the synthetic data. Second, the contextual signal itself may be relatively weak or diffuse in the feature space. The impact of COVID-19 is likely mediated through multiple behavioral changes (e.g., engagement patterns, assessment strategies), each contributing only partially to the overall effect. As a result, the signal is distributed across variables and may not be strongly identifiable by generative models optimizing global distributional fit. This leads to attenuation of context-specific effects in the synthetic data. Third, model-specific limitations further contribute to this behavior. For example, probabilistic graphical model-based SDGs (e.g., Bayesian Networks) encode dependencies through local conditional structures and may fail to capture higher-order or nonstationary effects spanning multiple variables and time periods. Neural generative models such as CTGAN can, in principle, model more complex interactions, which may explain their closer alignment with the findings of [44], but it still lacks explicit mechanisms to enforce consistency of context-dependent patterns across temporal slices.

Consequently, context-specific effects observed in real data are either attenuated or inconsistently represented in synthetic data, resulting in the absence of a systematic "shared context'' pattern. Indeed, across all SDGs, there is no consistent trend in the differences between the metric values for AY 2018–2019 vs. AY 2019–2020 and AY 2019–2020 vs. AY 2020–2021, reinforcing the conclusion that unmodeled contextual factors are not reliably preserved.

Another finding reported in [44] concerns stable learning indicators: these are the features that stay in the top important features irrespective of the context changes. They reported the overall level of activity features (Total number of sessions and Total session duration) as the most stable ones, followed by the features representing the regularity of study (Constancy of clicks and Constancy of session length). The replication using synthetic data reveals similar patterns, with overall level of activity features – Total number of sessions and Total session duration – emerging as the most stable, particularly for the CTGAN and TVAE models across SDGs. In contrast, the regularity of study features show less consistent alignment: Constancy of clicks is stable when data is generated using the BayesNet or TVAE, while Constancy of session length is stable with the CTGAN and TVAE models. Among all models, TVAE shows the closest alignment with the original findings of [44], particularly regarding stable features per course: for Accountancy, these include Total number of sessions, Total session duration, and Constancy of clicks; for Global Economics, the stable fea-

5. DISCUSSION

When evaluating the feature distributions in the data (RQ1) and the prediction utility of synthetic data (RQ2), we found that the BayesNet consistently outperformed other SDGs. This model was able not only to generate data that closely matched the distribution of the real dataset (both marginal distributions and multivariate dependencies), but also to produce synthetic data that could be effectively used to train ML models for student success prediction. While close resemblance to real data may increase the risk of exposing sensitive information when identifiable or sensitive attributes are present [25], such resemblance can be advantageous in settings where only behavioral data is used (as in this study), as it enhances the practical utility of synthetic data in scenarios where access to real data is limited or where data sharing and cross-institutional collaboration are required. These results suggest that simpler statistical models can perform just as well as, or even better than, more complex deep learning approaches for synthetic data generation in LA. Consistent with our findings, prior research has also shown that statistical models – such as Bayesian networks and Gaussian multivariate/copula methods – can achieve performance on par with models trained on real data [9, 51, 25]. Nevertheless, for categorical features, such as the binary study outcome, reweighting or resampling strategies may be necessary to stabilize the estimation of the outcome distribution and improve the fidelity of the synthetic data.

These insights extend beyond the field of LA. For example, Gunnarsson et al. [14] reported similar results when benchmarking deep learning methods for credit scoring, where simpler models were found to perform more reliably. Likewise, Dacrema et al. [10] questioned the added value of deep learning in recommender systems, highlighting cases where traditional methods offered more effective solutions.

Regarding the replication utility (RQ3), no single SDG consistently outperformed the others. Across the agreement metrics, all SDGs yielded results comparable to those reported in the original study [44]. The stable learning indicators identified with TVAE align most closely with the original findings, which contrasts with the conclusions from RQ1 and RQ2 suggesting the superiority of BayesNet. Nonetheless, the stable indicators derived from both the BayesNet and CTGAN also remain broadly consistent with the results of [44]. All the SDGs failed to replicate the COVID-19 effects reported by [44].

These findings suggest that even when an SDG performs well in terms of statistical resemblance and prediction utility, its replication utility may depend on the scope and depth of the replication being conducted. In our case, the differences in external COVID-19 effects across academic years that were evident in the real data did not fully emerge in the synthetic data. This may be attributable either to the effect sizes themselves – which were not explicitly examined in [44] – or to the fact that SDGs are unable to capture external and unpredictable factors such as COVID-19.

Limitations and Future work We recognize several limitations in this study. First, we employed a restricted set of SDGs, omitting potentially valuable models such as LLMs. We mitigated this limitation by focusing on the most widely used models in the literature with demonstrated performance – an aspect that LLMs currently lack in this context. Second, our analysis was limited in scope with respect to the range of ML models and statistical tests applied as well as two courses only, leaving a more comprehensive exploration for future research. Finally, we reproduced only the model agreement stability analysis of [44], excluding prediction drift and model performance stability analyses. We consider these to be promising directions for future investigation. Another future work direction is exploring more principled synthetic data generation strategies that explicitly account for heterogeneity across course contexts and learners, for example by modeling within-person behavioral patterns and hierarchical distributions (e.g., learners nested within courses) prior to aggregation. Such approaches may better preserve contextual effects and intra-learner structure, which have been shown to be critical for both predictability and explainability in educational data.

6. CONCLUSION

The fields of LA and EDM have shown how education can benefit from data-driven decision-making, particularly when aligned with pedagogical theories such as SRL. However, ethical and privacy concerns often limit access to authentic learning data, posing challenges for open science and collaborative research. Synthetic data – designed to statistically mirror real data – offers a promising alternative. Prior studies have primarily assessed the utility of synthetic data for its distributional similarity to real data and the predictive performance of ML models trained on it, compared with those trained on real data. This study extended prior research by evaluating the use of synthetic data for reproducing existing research, a crucial step toward reproducible LA. Grounded in SRL theory, our investigation highlighted how synthetic data can bridge pedagogy and the use of SDGs. To further support open LA, we provide a synthetic dataset that addresses the scarcity of publicly available LA data.

First, we demonstrated that synthetic data can effectively approximate the statistical properties of real data, with BayesNet achieving the strongest performance among the models tested. Second, student success prediction models trained on BayesNet-generated synthetic data achieved the highest predictive accuracy – at times even surpassing that of models trained on real data. Together, these findings highlight the advantage of statistical SDGs over deep learning–based approaches. Finally, all SDGs proved useful for reproducing the stability analysis conducted in [44], yielding stability metrics and stable features comparable to those in the original study. However, none of the SDGs successfully replicated the COVID-19 effects observed in the original research. This suggests that creating a versatile synthetic dataset capable of fully capturing external learning contexts remains highly challenging. Further research is needed to determine how best to select generative models that align with specific LA use cases. Nevertheless, the paper demonstrates how synthetic datasets can be used in the context of XAI stability, revealing aspects of their usefulness that are not captured by standard quality metrics.

Data availability The synthetic datasets used in this study have been made publicly available via Zenodo [42].

ABSTRACT

This study examines the stability and instructional context sensitivity of keystroke writing process features across a full academic year of middle school writing. Using 8,576 in-class writing sessions collected from two U.S. middle schools, we analyze whether writing-process indicators remain consistent within students over time and how they vary across instructional contexts. We define stability as within-student consistency of writing features across tasks and sensitivity as systematic variation associated with grade level and school. A broad set of features capturing fluency, pausing, revision, and engagement was extracted from students' longitudinal writing portfolios. We quantified stability using intraclass correlation coefficients and examined contextual sensitivity using linear mixed-effects models with random student-level intercepts. Results show that most features exhibit low stability within School x Grade cohorts, indicating substantial within-student variability across tasks. Only a small subset of low-level timing features related to word-level text production demonstrated moderate stability, whereas many revision- and engagement-related features varied systematically across instructional contexts. These findings clarify the measurement properties of keystroke-derived writing indicators and inform their appropriate use in longitudinal educational data mining applications.

Keywords

Keystroke logging, Writing process analytics, Longitudinal study, Feature stability, Contextual sensitivity

1. INTRODUCTION

Writing is a complex cognitive activity that involves coordinating planning, text production, and revision [13]. In educational settings, understanding how students engage in these processes is essential for assessing writing development and supporting instruction. However, traditional writing research has largely relied on final texts or observational methods, which provide limited insight into how writing unfolds over time [23]. Recent advances in keystroke logging technologies enable fine-grained capture of writers' real-time behaviors by recording keystrokes, pauses, and edits during composition [2, 22]. This data offers direct access to writing processes that are invisible in finished texts. These processes however, have become increasingly important in educational data mining (EDM) for applications such as learner modeling, performance prediction, and process-based feedback [7, 14].

Prior work shows that keystroke-derived features are educationally meaningful [37]. More proficient writers tend to produce text more fluently and pause strategically, whereas less proficient writers pause more frequently and revise differently [1, 33]. At the same time, writing processes are highly context-sensitive. Features such as total writing time, revision frequency, and output vary substantially across tasks, genres, and instructional conditions, while only a subset of low-level timing measures exhibit moderate stability across occasions [8, 32].

These findings highlight a fundamental measurement challenge for longitudinal writing analytics: some process features reflect relatively persistent student-level tendencies, whereas others primarily capture contextual adaptation [8]. This distinction matters even within a single instructional setting. As students encounter different tasks, genres, and instructional demands across an academic year, observed changes in their writing process features may reflect shifts in task context rather than genuine developmental growth. Without first establishing which features are stable within students across tasks and which vary systematically with context, longitudinal analyses risk conflating developmental change with task-specific effects, leading to misleading inferences about writing growth [2]. This motivates the present study's focus on measurement before modeling, characterizing the stability and contextual sensitivity of keystroke-derived features as a foundation for future longitudinal work.

This challenge is particularly salient for educational applications that aim to model writing development over time or deploy process-based analytics in classrooms [7, 14]. Be-

fore modeling growth or generating feedback, it is necessary to establish whether keystroke-derived features are interpretable across writing samples [2, 32]. Accordingly, this study adopts a measurement-focused perspective that precedes growth modeling. Rather than modeling change directly, we examine the stability and contextual sensitivity of writing process indicators in authentic classroom settings.

We address this goal through two research questions:

- **RQ1:** To what extent do keystroke-derived writing process indicators exhibit within-student consistency across tasks in students' longitudinal writing portfolios?
- **RQ2:** To what extent does variability in these indicators reflect systematic sensitivity to instructional context, specifically grade level, incoming academic proficiency, and school membership?

To answer these questions, we analyze longitudinal keystroke data collected from everyday classroom writing across an entire school year in two middle schools. By characterizing which process features exhibit within-cohort stability and which vary systematically with context, this work provides a principled foundation for longitudinal learner modeling and process-aware educational data mining in real-world instructional environments [2, 36].

2. BACKGROUND

2.1 Writing process features

Research on writing processes has consistently shown that keystroke-derived features capture meaningful aspects of how students compose text, including productivity, fluency, pausing, and revision behavior [22, 33]. Across populations, more proficient writers tend to write more fluently, produce longer bursts of text, and pause less frequently, reflecting more efficient translation of ideas into language [15, 18]. Fluency-related measures, in particular, have been repeatedly linked to writing quality and performance in both classroom and assessment contexts [5].

Pausing behavior provides additional insight into cognitive processing during composition. Skilled writers typically exhibit shorter pauses at character, word, and sentence boundaries. This is consistent with more automatic lexical access and smoother coordination between planning and production [26, 35]. Burst length, the amount of text produced between pauses, has emerged as a robust indicator of writing fluency, with longer bursts associated with higher-quality writing across multiple studies [2, 5].

Revision behavior presents a more complex picture. Prior work suggests that stronger writers engage in more strategic, higher-level revisions that reorganize or clarify meaning, while less skilled writers tend to make frequent surface-level edits during drafting [11, 34]. Although revision features are informative, their interpretation often depends strongly on task demands and instructional context [9]. Together, this body of work demonstrates that keystroke-derived features capture meaningful variation in writing processes and motivate applications in learner modeling, performance prediction, and process-based feedback within educational data mining [7, 16].

2.2 Stability of writing process features

A central methodological question in writing process research concerns whether keystroke-derived features represent stable characteristics of writers or fluctuate substantially across tasks. Early work emphasized that many process measures reflect multiple interacting cognitive and situational factors and cautioned against assuming direct mappings to stable traits [16, 28]. However subsequent empirical studies have demonstrated that stability varies widely across features.

In assessment contexts for example, Deane and Zhang showed that only a limited subset of keystroke features exhibits moderate test– retest reliability across essay prompts, while many others display low consistency [37]. Crucially, these stable features were also the ones that generalized across tasks in predictive models, whereas highly variable features failed to support robust inference about writing ability [10]. This finding underscores that stability is not merely a psychometric concern but a prerequisite for longitudinal interpretation and modeling.

Longitudinal evidence from text-based writing research reinforces the importance of this distinction between stability and change. Using mixed-effects models over a large learner corpus, Lei, Wen, and Yang showed that development in syntactic complexity unfolds gradually and is characterized by substantial within-writer variability over time [21]. Their findings emphasize that longitudinal inference depends on features that are sufficiently stable to support growth modeling, while still allowing for uneven, context-dependent trajectories of change.

Related results have been reported in adult and second-language writing. Choi and Deane found that despite substantial within-writer variability, certain low-level timing features remained relatively stable across tasks and time points and were meaningfully related to writing quality [6]. Across studies, a consistent pattern emerges: low-level fluency measures (e.g., typing speed, within-word pause duration) tend to behave as writer-specific tendencies, whereas higher-level features related to planning, revision, or sentence-level pausing are more sensitive to task characteristics [1, 37].

2.3 Contextual sensitivity and task effects

Alongside work on stability, a substantial literature demonstrates that writing processes are highly sensitive to task and context. Writing behavior varies with prompt complexity, genre, topic familiarity, time constraints, and instructional conditions [4, 17]. Experimental studies manipulating task difficulty show that output-related features and revision frequency increase substantially for more demanding tasks, while core timing features such as average inter-key interval remain comparatively stable [1].

At the same time, longitudinal writing development is inherently context-sensitive. A study demonstrated that trajectories of syntactic complexity growth vary systematically with instructional and contextual factors, even when mod-

eled at scale [21]. This finding highlights a key challenge for longitudinal writing research: apparent change may reflect shifts in task demands or learning contexts rather than underlying development, underscoring the need to interpret longitudinal patterns in relation to both stability and context.

Genre effects further highlight contextual sensitivity. Argumentative writing typically elicits longer pauses and more revisions than narrative writing, reflecting increased planning and evaluation demands [4, 11]. In assessment settings, researchers have cautioned that process measures observed for one prompt may not generalize to another, limiting their interpretability across occasions [10, 36]. For longitudinal analyses, this presents a key challenge: observed changes in process features may reflect contextual variation rather than genuine development.

2.4 Measurement & modeling

Interest in writing process data has grown across research on learner modeling and instructional support. Keystroke-derived features have been incorporated into predictive models of writing quality and shown to add explanatory power beyond static text features [6, 7]. Process features have also been explored as signals for real-time feedback and formative analytics in writing support systems [22, 29].

Broader efforts in human-computer interaction have also examined the design of intelligent writing support systems. A study proposed a comprehensive design space for writing assistants organized around user, task, technology, interaction, and ecosystem dimensions, highlighting writing efficiency and proficiency as key user-facing considerations [20]. The measurement properties of keystroke-derived features examined in the present study are directly relevant to such systems, as reliable process signals are a prerequisite for effective real-time writing support.

However, a recurring concern in this line of work is the validity of process features across contexts. If the meaning of a feature varies substantially across genres or task conditions, its use in general-purpose models becomes problematic [1, 36]. Modeling applications therefore require a principled understanding of which features are robust across contexts and which require contextualized interpretation.

Prior research establishes that writing process features capture skill-related patterns, vary widely in stability, and are strongly influenced by task context. What remains underexplored is how these features behave across broader instructional contexts, such as grade level and school, within naturalistic longitudinal classroom data. This study addresses that gap by systematically examining the stability and contextual sensitivity of keystroke-derived writing process features in everyday classroom writing, providing a measurement foundation for longitudinal modeling and process-aware analysis.

3. DATASET

3.1 Data Collection

This study uses longitudinal keystroke data collected via Writing Observer, a research platform integrated into Google Docs and deployed in two U.S. public middle schools. Writing Observer is a suite of tools designed to support classroom orchestration in writing-to-learn tasks. The platform unobtrusively captures real-time writing data at the keystroke level, recording students' editing behaviors, reading activity, and document interactions from start to finish of each writing session. It is also designed to integrate into existing learning management systems to track class enrollments, assignments, and evaluations, enabling monitoring of writing practices within and across assignments. Since students contributed multiple writing sessions over an academic year, the resulting dataset supports analysis of within-student consistency and contextual variation in writing-process features across authentic classroom tasks.

All data collection was conducted in accordance with institutional research ethics requirements. The study operated under IRB approval, with students participating under appropriate consent and assent procedures. All records were pseudonymized prior to analysis, and no personally identifiable information is reported.

3.2 Participants

The study participants included 423 middle school students in Grades 7 and 8 from two U.S. public schools who participated during the 2023–2024 academic year. One school was a large urban middle school in Utah, and the other was a suburban middle school in Pennsylvania. Together, these schools provided a diverse instructional context while remaining comparable in grade span and curricular structure.

The writing activities were part of regular classroom instruction, primarily in English Language Arts (ELA) courses, with additional writing in subjects such as science and social studies. Assignments included narrative, argumentative, and informative writing, as well as text-dependent analysis, and non-ELA writing such as lab reports and class notes. Session durations varied and were computed from the first to the last logged keystroke event within each document. Writing prompts were not standardized and varied naturally by grade, teacher, genre, and topic, reflecting authentic classroom practice rather than controlled assessment conditions.

We collected a total of 9,831 writing-session logs. After excluding documents with fewer than 50 words, the final corpus consisted of 8,576 sessions (3,641 from School 1 and 4,935 from School 2). All data were collected under appropriate institutional approvals, and logs were de-identified prior to analysis. Table 1 summarizes sample sizes by school, grade, and dataset. Figures 1 and 2 show the distribution for both schools.

Also, we collected the incoming proficiency scores of all the students from the 2022-2023 academic year which were binned into four categories (1 = Below Basic, 2 = Basic, 3 = Proficient, 4 = Advanced). Given the absence of Below-Basic students in School 2 and their low numbers in School 1, Below Basic group was excluded to maintain comparability across schools.

Gender distribution across cohorts was as follows: School 1 Grade 7 had 70 female and 40 male students; School 1 Grade

8 had 47 female and 51 male students; School 2 Grade 7 had 31 female and 30 male students; and School 2 Grade 8 had 75 female and 79 male students.

Table 1: Sample sizes by school, grade, and number of documents

School	Grade 7		Grade 8	
	Students	Docs	Students	Docs
1	110	1840	98	1801
2	61	989	154	3946

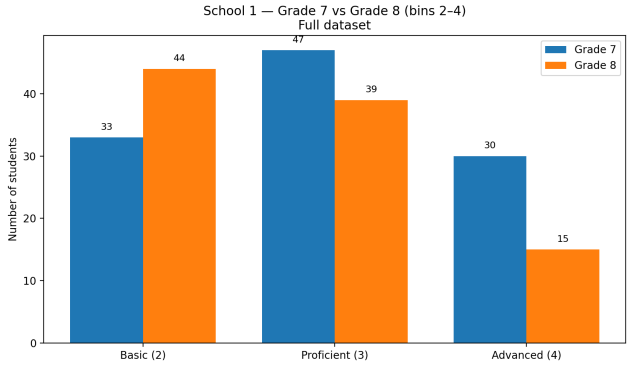

Figure 1: School 1 (Grade 7 and 8) Full State Assessment Scores

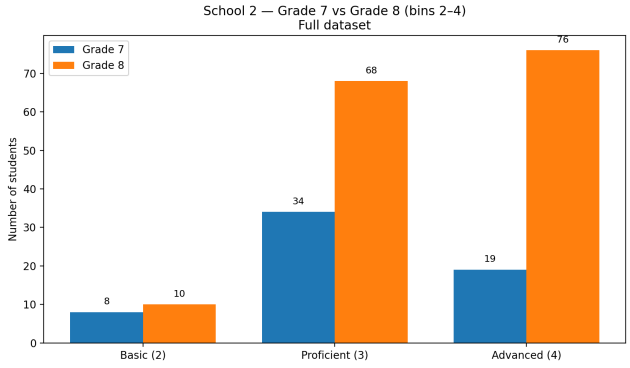

Figure 2: School 2 (Grade 7 and 8) Full State Assessment Scores

3.3 Feature Extraction

Each keystroke log consists of a timestamped sequence of writing events, including the character insertions, deletions, pauses, and navigation actions. Pauses were inferred from inter-keystroke intervals (IKIs), and revision behavior was identified through insertion–deletion patterns in the event stream [2, 22].

From these logs, we derived a set of keystroke-based process features describing how students generated, revised, and interacted with text. Following prior writing-process research (Section 2), features were organized into four behavioral dimensions: fluency, revision, complexity, and engagement [1, 8, 10, 36]. In total, ten frequency-based features (capturing how often actions occurred) and fourteen time-based features (capturing pause durations and temporal dynamics) were computed. We summarize the feature families:

1. **Fluency:** Features capturing transcription efficiency and writing flow, including the number of inserts, in-word inserts, between-word inserts, before-word inserts, word-start inserts, and pause measures such as IKI between inserts, within-word IKI, between-word IKI, before-word IKI, and word-start IKI [1, 22].
2. **Revision:** Features describing editing and text modification behavior, including before-word inserts, total edits (insertions + deletions), starting and continuing backspaces, edit duration, and pause measures associated with deletion activity (IKI starting backspace, IKI continuing backspace) [2, 10].
3. **Complexity:** Features reflecting structural and syntactic elaboration during writing, including clause-break inserts, minor punctuation inserts (e.g., commas, parentheses), and associated pause measures at clause boundaries and minor punctuation (IKI at clause break, IKI at minor punctuation) [1, 4].
4. **Engagement:** Features that capture non-typing interactions with the document, including overall menu time, reading time (inactive but focused time), navigation time (cursor, scrolling, arrow keys), and total active writing time [35].

Time-based features were log-transformed using $\log(1+x)$ to mitigate heavy-tailed pause distributions, and pauses longer than 120 seconds were truncated to exclude off-task intervals [1, 22]. For each applicable time-based feature, the mean, median, standard deviation, and variance were computed, yielding a total of 44 features used in analysis [2, 10]. Although a broader feature set was available, this study focuses on core indicators of fluency, revision, complexity, and engagement that are most relevant to examining longitudinal stability and contextual sensitivity [1, 8].

4. METHODS

Our analysis addresses two research questions using complementary statistical approaches. RQ1 examines the stability of keystroke-derived writing process features within cohorts using variance decomposition via intraclass correlation, while RQ2 examines sensitivity to contextual factors using linear mixed-effects modeling [12, 27].

4.1 Data Preparation and Cohort Definition

Writing process features were extracted from document-level writing logs, with multiple writing samples available per student. Because proficiency-level information was not available at the document level, student proficiency-level labels were obtained from a separate roster summary and merged onto document-level records using anonymized student identifiers.

Writing samples without an associated proficiency-level label were excluded from further analysis. Analyses were conducted separately for each school, and within each setting,

data were further stratified by grade level. All results reported for RQ1, therefore, reflect within-cohort analyses, defined by a specific combination of school and grade. To ensure reliable estimation of student-level effects, analyses were restricted to students who contributed at least two writing sessions within a given cohort, and only features present and numerically valid within that cohort were included.

4.2 RQ1: Intra-Class Correlation Analysis for Feature Stability

RQ1 investigates the extent to which keystroke-derived writing process features exhibit stable, student-specific structure within cohorts, as opposed to variability across writing samples produced by the same student. Stability is quantified using the intraclass correlation coefficient (ICC), which decomposes total variance into between-student and within-student components [12, 24]. In the context of writing-process analysis, stability indicates whether a feature reflects a persistent student-level tendency rather than transient task-specific behavior.

For each writing process feature and for each school × grade cohort, we estimated the intraclass correlation coefficient (ICC) using a random-intercept formulation:

$$y_{ij} = \mu + u_i + \varepsilon_{ij}, \tag{1}$$

where y_{ij} denotes the value of a given writing-process feature for student i on writing task j, μ is the overall mean, $u_i \sim \mathcal{N}(0, \sigma^2_{\text{student}})$ represents a student-specific random intercept capturing stable between-student differences, and $\varepsilon_{ij} \sim \mathcal{N}(0, \sigma^2_{\text{within}})$ captures within-student variability across tasks, , where $\sigma^2_{\text{student}}$ and σ^2_{within} denote the between-student and within-student variance components, respectively.

We computed the intraclass correlation coefficient (ICC) as:

$$\text{ICC} = \frac{\sigma^2_{\text{student}}}{\sigma^2_{\text{student}} + \sigma^2_{\text{within}}}, \tag{2}$$

which represents the proportion of total variance attributable to stable between-student differences. Under this random-intercept formulation, total variance is fully decomposed into between-student and within-student components, such that their sum represents the total variability in the feature. An ICC close to 1 indicates that a feature is highly stable within students across writing tasks, whereas an ICC near 0 indicates that most variability arises from task-to-task fluctuations within students.

For each feature, point estimates of the ICC were obtained using a random-intercept mixed-effects model estimated via restricted maximum likelihood (REML) [31]. When model estimation was unstable, point estimates were computed using an ICC estimator based on a one-way analysis of variance [30]. To quantify uncertainty, we computed ICCs and corresponding 95% confidence intervals for each feature using all available writing sessions. Following established conventions, ICC values were categorized as indicating poor (< 0.20), fair (0.20–0.40), moderate (0.40–0.60), or high (≥ 0.60) stability [19].

This analysis enables ranking writing-process features by their degree of longitudinal consistency and identifying which features function as persistent student-level signatures versus those dominated by task-specific variation. Establishing this distinction is a prerequisite for meaningful longitudinal modeling of writing development, as features that lack sufficient stability cannot be reliably interpreted as indicators of student growth.

4.3 RQ2: Modeling Contextual Sensitivity

RQ2 examines how writing-process features vary systematically with school context, grade level, and academic proficiency, while accounting for repeated observations from the same student [31, 3]. Specifically, RQ2 asks whether a portion of observed feature variance can be explained by known contextual factors rather than treated as undifferentiated task noise. Each feature was modeled using a linear mixed-effects framework with fixed effects for contextual variables and a random student-level intercept. Although writing-process features may exhibit complex or nonlinear patterns over time, the present analysis uses a linear mixed-effects framework because contextual predictors are modeled as categorical fixed effects, allowing for flexible, non-monotonic differences across groups without imposing a specific functional form.

For each writing-process feature, we fit the following model:

$$y_{ij} = \beta_0 + \beta_1 \text{School}_i + \beta_2 \text{Grade}_i + \beta_3 \text{StateScore}_i + b_i + \varepsilon_{ij},$$

where y_{ij} is the feature value for student i on writing task j, β_0 is the intercept, and β_1, β_2, and β_3 represent fixed effects of school, grade level, and incoming academic proficiency, respectively. The term $b_i \sim \mathcal{N}(0, \sigma^2_{\text{student}})$ captures student-specific deviations from the population mean, and $\varepsilon_{ij} \sim \mathcal{N}(0, \sigma^2_{\text{residual}})$ represents residual variability [31, 3].

We treated school, grade level, and incoming academic proficiency as categorical fixed effects to allow for non-linear and non-monotonic differences across groups [31]. Academic proficiency was operationalized using a categorical state assessment score with four ordered levels.

To identify school effects, we fit models across schools and grade levels, ensuring that the school predictor varied within each subset. We estimated all models using restricted maximum likelihood and included only students who had at least two writing sessions [31]. Subsets with insufficient numbers of students or insufficient variation in predictors were excluded.

For each fitted model, we report fixed-effect estimates, standard errors, z-statistics, and approximate two-sided p-values based on normal approximations [29]. We also report variance components for the student-level random intercept and the residual term to contextualize the relative contribution of between- and within-student variability.

5. RESULTS

5.1 RQ1: Feature Stability Within Cohorts

This section reports results for RQ1, which examines the stability of keystroke-derived writing process features within School × Grade cohorts. We quantify stability using intraclass correlation coefficients (ICCs), where higher values

Table 2: Feature-Level ICCs for School 1 – Grade 7

Feature	ICC	Stability
meanLogWordStartInsertTime	0.448	Moderate
meanLogBeforeWordInsertTime	0.288	Fair
stdLogBetweenWordInsertTime	0.184	Poor
varLogContinuingBackspaceTime	0.104	Poor
varLogEditTime	0.094	Poor
varLogBeforeWordInsertTime	0.082	Poor
stdLogWordStartInsertTime	0.074	Poor
overallNavigationTime	0.056	Poor

indicate greater consistency of a feature across multiple writing samples produced by the same student, relative to variability between students within the same cohort.

Across all cohorts, a substantial proportion of features yielded ICC values of 0 (or effectively 0), indicating no detectable between-student variance after accounting for within-student variability. Tables 2–5 report only features with non-zero ICC estimates; all omitted features had ICC = 0 and are therefore not interpretable as stable individual-level measures in these contexts. Overall, feature-level stability varied markedly across schools, grade levels, and feature types. The majority of features exhibited Poor stability, with only a small subset, primarily low-level insertion timing features, demonstrating Moderate or High stability, most consistently in School 2.

5.1.1 School 1 – Grade 7

In School 1, Grade 7, the writing process features demonstrated overwhelmingly low stability (Table 2). Of the 41 features examined, most produced ICC values of 0, indicating that variability was almost entirely within students across writing tasks rather than between students. Among the features with non-zero ICCs, only meanLogWordStartInsertTime reached Moderate stability (ICC = 0.448). meanLogBeforeWordInsertTime showed Fair stability (ICC = 0.288), while all remaining reported features, including measures of timing variability, backspacing behavior, and navigation time, exhibited Poor stability (ICC < 0.20).

These results suggest that, in this cohort, most writing-process features do not function as stable student-level characteristics and instead fluctuate substantially across writing tasks.

5.1.2 School 1 – Grade 8

In School 1, Grade 8, stability patterns remained limited, though a small number of features demonstrated modest increases relative to Grade 7 (Table 3). As in Grade 7, the majority of the features analyzed yielded ICCs of 0 and are not shown. Two within-word insertion timing features, meanLogInWordInsertTime (ICC = 0.494) and medianLogInWordInsertTime (ICC = 0.484), demonstrated Moderate stability, while medianLogStartingBackspaceTime reached Fair stability (ICC = 0.386). All other reported features exhibited Poor stability, and no features achieved High stability.

Overall, while some fine-grained timing features became more consistent in Grade 8, feature-level stability in School 1 remained sparse and highly selective.

Table 3: Feature-Level ICCs for School 1 – Grade 8

Feature	ICC	Stability
meanLogInWordInsertTime	0.494	Moderate
medianLogInWordInsertTime	0.484	Moderate
medianLogStartingBackspaceTime	0.386	Fair
meanLogClauseBreakInsertTime	0.175	Poor
varLogContinuingBackspaceTime	0.144	Poor

Table 4: Feature-Level ICCs for School 2 – Grade 7

Feature	ICC	Stability
medianLogInWordInsertTime	0.681	High
meanLogInWordInsertTime	0.679	High
meanLogBetweenWordInsertTime	0.620	High
medianLogBetweenWordInsertTime	0.594	Moderate
medianLogWordStartInsertTime	0.589	Moderate
meanLogWordStartInsertTime	0.567	Moderate
medianLogStartingBackspaceTime	0.504	Moderate
meanLogStartingBackspaceTime	0.462	Moderate
meanLogBeforeWordInsertTime	0.266	Fair
stdLogMinorPunctInsertTime	0.145	Poor
varLogContinuingBackspaceTime	0.142	Poor
varLogBeforeWordInsertTime	0.042	Poor
stdLogClauseBreakInsertTime	0.032	Poor

5.1.3 School 2 – Grade 7

In contrast, School 2 Grade 7 exhibited markedly higher stability across several features (Table 4). Although many of the 41 features still yielded ICC values of 0, a larger subset demonstrated meaningful between-student consistency. Three features, medianLogInWordInsertTime (ICC = 0.681), meanLogInWordInsertTime (ICC = 0.679), and meanLogBetweenWordInsertTime (ICC = 0.620), reached High stability, indicating strong within-student consistency across writing sessions. Several additional features related to word-start insertion and starting backspace timing demonstrated Moderate stability (ICC ≈ 0.50–0.59). Despite this, higher-order variability measures (e.g., variance-based timing features and punctuation timing variability) continued to show Poor stability or zero ICCs.

These results suggest that, in this context, micro-temporal production behaviors may reflect relatively stable individual writing signatures, while broader variability-based features do not.

5.1.4 School 2 – Grade 8

In School 2, Grade 8, overall stability declined relative to Grade 7, though it remained higher than in School 1 (Table 5). As in other cohorts, many of the 41 features analyzed had ICCs of 0 and are omitted. Two within-word insertion timing features, meanLogInWordInsertTime (ICC = 0.589) and medianLogInWordInsertTime (ICC = 0.568), retained Moderate stability, while meanLogClauseBreakInsertTime demonstrated Fair stability (ICC = 0.315). All remaining reported features exhibited Poor stability, and no features reached High stability.

These findings indicate that even within the same school context, feature stability can attenuate with grade level and

Table 5: Feature-Level ICCs for School 2 – Grade 8

Feature	ICC	Stability
meanLogInWordInsertTime	0.589	Moderate
medianLogInWordInsertTime	0.568	Moderate
meanLogClauseBreakInsertTime	0.315	Fair
stdLogWordStartInsertTime	0.124	Poor
stdLogContinuingBackspaceTime	0.106	Poor
stdLogClauseBreakInsertTime	0.059	Poor
stdLogStartingBackspaceTime	0.054	Poor
overallActiveWritingTime	0.015	Poor

that stable features become increasingly restricted to specific low-level timing measures.

5.1.5 Summary of RQ1 Findings

Across all School × Grade cohorts, there are three key patterns that emerged:

- Zero ICCs are the norm: In every cohort, a substantial number of the 41 analyzed features yielded ICC values of 0, indicating that most writing-process features do not exhibit stable between-student differences.
- Stability is highly feature-specific: When stability emerged, it was largely confined to within-word and word-initial insertion timing features, rather than variability based or aggregate measures.
- Stability is context-dependent: School 2, particularly Grade 7, exhibited systematically higher stability than School 1, suggesting that instructional or institutional context may shape the consistency of writing processes.

Taken together, these results indicate that most keystroke-derived writing process features should not be treated as stable individual traits. Instead, stability appears rare, selective, and context-dependent, motivating the mixed-effects analyses in RQ2, which explicitly examine how contextual factors explain systematic variation in writing process behavior.

5.2 RQ2: Sensitivity to Contextual Factors

RQ2 examined whether variability in keystroke-derived writing process features can be systematically explained by contextual factors, specifically, school, grade level, and incoming academic proficiency, after accounting for repeated observations from the same student. To address this question, we fit a series of linear mixed-effects models, one per feature, including fixed effects for school, grade, and proficiency level, and a random intercept for student. All models were fit on the Full dataset, pooling Grades 7 and 8 across both schools.

5.2.1 Overall Patterns of Contextual Sensitivity

Across features, contextual sensitivity varied substantially by feature type. In general, incoming academic proficiency exhibited more consistent associations with writing process behavior than grade level and school membership. This pattern suggests that observed variation in writing processes reflects proficiency-related differences more than developmental or school-specific artifacts. Random intercept variances for students were consistently non-zero across models, confirming substantial between-student variability and justifying the use of mixed-effects modeling to account for repeated writing samples per student. Throughout the following subsections, fixed-effect coefficients are reported alongside back-transformed percentage differences (computed as $e^{\hat{\beta}} - 1$), which reflect multiplicative change in the original pause durations given that features were log-transformed prior to modeling.

5.2.2 Grade-Level Effects

Grade-level effects were observed for several timing-based features. In particular, Grade 8 students often exhibited shorter within-word insertion times than Grade 7 students. These effects were typically negative in direction, indicating increased efficiency or fluency with advancing grade level. However, grade effects were not universal across all features and were generally modest in magnitude, suggesting that developmental differences manifest more strongly in fine-grained timing behaviors than in global duration measures. Table 6 summarizes features with significant grade-level effects.

Table 6: Significant Grade-Level Effects (Grades 8 vs. 7)

Feature	β	Interpretation
Median In-word Pause	−0.03	3% shorter
Mean In-word Pause	−0.03	3% shorter
Std. In-word Pause	−0.02	2% less varying
Median Clause-break Pause	−0.05	5% shorter
Mean Clause-break Pause	−0.05	5% shorter
Var. Clause-break Pause	−0.21	19% less varying
Median Edit Pause	+0.02	2% longer

5.2.3 Proficiency Effects

Academic proficiency demonstrated clearer and more interpretable associations with writing process features than grade level. For multiple fine-grained timing features, the highest proficiency level (Level 4) was associated with systematically faster within-word insertion behaviors relative to the Basic proficiency group, while Level 3 effects were generally small and non-significant. These patterns indicate that keystroke-level timing measures capture meaningful differences in writing fluency linked to incoming academic proficiency. Importantly, proficiency effects were not uniformly incremental across adjacent levels. In several cases, only the highest proficiency group differed significantly from the reference group, indicating potential threshold effects rather than linear progression across proficiency bands. Table 7 summarizes features with significant proficiency effects.

Table 7: Significant Proficiency Effects (Level 4 vs. Level 2)

Feature	β	Interpretation
Median In-word Pause	−0.04	4% shorter
Mean In-word Pause	−0.05	5% shorter
Std. In-word Pause	−0.02	2% less varying
Median Clause-break Pause	−0.08	8% shorter
Mean Clause-break Pause	−0.08	8% shorter
Var. Clause-break Pause	+0.19	21% more varying
Mean Minor Punct. Pause	−0.080	7.7% shorter

5.2.4 School Effects

School membership explained relatively little variance in writing process features after controlling for grade and proficiency. Most school-related coefficients were small and non-significant, indicating that differences in writing processes were largely consistent across institutional contexts. This finding supports the generalizability of keystroke-based process measures across schools and suggests that observed behavioral differences are not driven by local instructional or institutional idiosyncrasies. Table 8 summarizes the two features with significant school effects.

Table 8: Significant School Effects (School 2 vs. School 1)

Feature	β	Interpretation
Std. In-word Pause	-0.02	2% less varying
Mean Minor Punct. Pause	-0.09	8.6% shorter

5.2.5 Summary of RQ2 Findings

Taken together, the RQ2 results demonstrate that while many writing process features exhibit substantial within-student variability, a subset shows systematic sensitivity to meaningful contextual factors, particularly incoming academic proficiency and, to a lesser extent, grade level. Fine-grained timing features appear especially informative for distinguishing writing behaviors associated with higher proficiency, whereas global duration measures reflect engagement-related differences. These findings complement the stability analyses in RQ1 by showing that writing process features may be individually variable yet still contextually interpretable when modeled appropriately.

6. DISCUSSION

This study examined keystroke-derived writing-process features from two complementary perspectives: their stability across students and tasks (RQ1) and their systematic sensitivity to contextual factors such as grade level, school, and incoming academic proficiency (RQ2). Taken together, the findings reveal a nuanced picture in which most writing process features are highly variable at the individual level, yet a subset remains meaningfully interpretable when contextualized appropriately.

6.1 Limited Stability of Writing Process Features

The RQ1 analyses demonstrate that zero or near-zero ICCs were the norm across all School × Grade cohorts. For a large proportion of the 41 features examined, between-student variance was effectively absent once within-student variability across writing tasks was accounted for. This finding challenges the common assumption, implicit in many learning analytics applications, that keystroke-derived features can be treated as stable, student-specific traits.

When stability did emerge, it was highly feature-specific, largely confined to low-level temporal production measures, such as within-word and word-initial insertion times. These features plausibly reflect motor–cognitive coordination processes that are less sensitive to task content and genre, making them more likely to persist across writing contexts. In contrast, higher-order variability measures, revision timing dispersion, and aggregate duration features consistently exhibited poor or zero stability, suggesting that these measures are strongly task-dependent rather than student-specific.

Importantly, stability was also context-dependent. School 2, particularly Grade 7, exhibited substantially higher stability than School 1, indicating that instructional context, curriculum alignment, or writing task design may shape the consistency with which students express their writing processes. This variability cautions against generalizing stability findings from a single institutional setting and underscores the importance of reporting stability estimates alongside proposed writing-process indicators. This finding does not contradict the RQ2 result showing no significant school effect. The two analyses ask different questions about the data: RQ2 examines whether students in different schools write differently on average, while RQ1 examines whether individual students write consistently across tasks. A school context can produce similar average writing behaviors across institutions while still shaping how consistently individual students express those behaviors from task to task.

6.2 Reconciling Instability With Contextual Sensitivity

At first glance, the widespread instability observed in RQ1 may appear to undermine the usefulness of keystroke-derived writing process features. However, the RQ2 results clarify that lack of individual-level stability does not imply lack of interpretability. While many features fluctuate substantially across students within tasks, a subset shows systematic sensitivity to meaningful contextual factors, particularly incoming academic proficiency and grade level.

Fine-grained timing features, especially within-word and word-initial insertion measures, showed consistent associations with both grade and proficiency. Higher-grade and higher proficiency students tended to exhibit faster insertion behaviors, aligning with theoretical accounts of increased writing fluency and automatization with development and skill acquisition. These findings suggest that although such features may not function as stable individual signatures, they nonetheless capture reliable group-level differences tied to developmental and proficiency-related factors.

By contrast, macro-level duration features, such as overall active writing time, followed a different pattern. These features showed limited grade sensitivity but were associated with proficiency in ways that suggest differences in engagement or persistence rather than efficiency. Notably, higher-proficiency students spent more time actively writing, indicating that longer writing durations should not be interpreted simplistically as inefficiency, but rather as potentially reflecting sustained effort or deeper engagement.

This finding resonates with and extends prior work on revision behavior in writing support systems. A study demonstrated that revision patterns captured from writing tool logs are meaningful and vary systematically across learners, including differences tied to gender and feedback condition [25]. Our results complement this by showing that revision features are among the least stable across tasks at the individual level, suggesting that longitudinal pipelines relying on revision indicators should account for substantial within-

student variability rather than treating revision behavior as a fixed learner characteristic.

6.3 Implications for Writing Analytics and Educational Dashboards

Together, these findings have important implications for the design and interpretation of writing analytics systems. First, they suggest that keystroke features should not be universally treated as stable learner traits, especially when used for longitudinal profiling or individual diagnosis. Most features are better understood as context-sensitive behavioral indicators that respond to task demands, instructional conditions, and developmental factors.

Second, the results highlight the value of mixed-effects modeling frameworks for research on the writing process. By explicitly modeling both within-student variability and contextual predictors, such approaches allow researchers and practitioners to extract meaningful patterns from features that would otherwise appear noisy or unreliable at the individual level.

Finally, the differential behavior of fine-grained timing features versus aggregate duration measures suggests that feature families serve distinct interpretive roles. Low-level timing features may be well-suited for examining fluency and automatization, while duration-based features may provide insight into engagement, persistence, or strategic effort. Analytics systems and dashboards should therefore avoid aggregating heterogeneous features into undifferentiated indices and instead support feature-specific interpretation.

7. CONCLUSIONS

This paper examined the measurement properties of keystroke-derived writing process features in authentic classroom settings, focusing on their within-cohort stability and sensitivity to contextual factors. Using a large corpus of middle school writing sessions, we showed that most writing process features exhibit low or zero stability within School × Grade cohorts, reflecting substantial within-student variability across writing tasks. Only a small subset of fine-grained timing features related to word-level text production demonstrated moderate stability, and high stability was rare and strongly context-dependent.

In contrast, many writing process features varied considerably across writing sessions. Mixed-effects analyses revealed that, for a limited set of features, this variability aligns systematically with incoming academic proficiency and grade level, rather than reflecting undifferentiated noise. In particular, within-word insertion timing features showed consistent associations with proficiency, with higher-proficiency students exhibiting faster text production. Grade-level effects were present but modest, suggesting that writing process development during middle school unfolds gradually and that much observed variability reflects situational adaptation rather than rapid developmental change. After controlling for grade and proficiency, school-level effects were small and largely non-significant, supporting the generalizability of keystroke-based process measures across institutional contexts.

Taken together, these findings clarify an important measurement distinction: keystroke-derived writing-process features do not uniformly serve as stable student-level indicators. Some features provide relatively consistent signals within cohorts, while others primarily capture context-responsive behavior. This distinction is critical for longitudinal research, as features dominated by within-student variability cannot be interpreted as reliable indicators of enduring writing characteristics when analyzed in isolation.

The primary contribution of this study is methodological. Rather than modeling writing growth directly, we establish which classes of process features are sufficiently stable to support longitudinal interpretation and which require explicit contextual modeling. This groundwork enables more principled feature selection for future growth modeling, evaluation, and intervention studies in educational data mining.

From a practical perspective, the results suggest complementary roles for different feature types in educational tools. Features with higher within-cohort stability may support longitudinal monitoring of foundational writing processes, whereas context-sensitive features may serve as indicators of task-specific difficulty, instructional demands, or adaptive strategy use. Interpreting these signals jointly allows educators and researchers to distinguish enduring writing patterns from situational challenges.

While future work is needed to link process features to writing quality, extend analyses across longer time scales, and replicate findings in broader populations, this study provides a focused and principled analysis of writing-process measurement in real classroom contexts. Overall, the results demonstrate that keystroke-derived writing data contain both reliable structure and meaningful variability. Advancing longitudinal writing analytics will depend on leveraging the former while modeling the latter with appropriate attention to context.

7.1 Limitations and Future Work

While this study provides a systematic characterization of the stability and contextual sensitivity of keystroke-derived writing process features, several limitations should be acknowledged, along with directions for future research.

7.1.1 Absence of Writing Outcome Measures

A primary limitation of this study is the absence of direct measures of writing quality or learning outcomes. Although we identify features that exhibit greater stability within School × Grade cohorts (RQ1) and others that vary systematically with contextual factors such as grade level and incoming academic proficiency (RQ2), we do not evaluate whether these patterns correspond to improved writing performance or desirable writing behaviors. Stability alone does not imply educational value, and context sensitivity does not necessarily indicate instructional relevance.

Without outcome measures such as essay scores, rubric-based assessments, or teacher feedback, it is not possible to determine whether stable features reflect productive writing habits, emergent fluency, or merely idiosyncratic behaviors. Future work will integrate outcome measures to examine how stable and context-sensitive process features relate to

writing quality and development. In particular, longitudinal growth models linking changes in writing process features to changes in writing performance will be critical for validating the educational significance of the process indicators identified in this study.

7.1.2 Limited Temporal Scope

The data analyzed in this study span approximately one academic year, which constrains conclusions about long-term stability and developmental change. Features that appear stable over this time frame may still evolve over longer periods, particularly across major instructional transitions or shifts in curricular emphasis. As a result, stability within a single school year should not be interpreted as permanence or trait-like invariance.

Longer-term longitudinal studies, especially those tracking students across multiple grade levels or school transitions, would help determine how writing process features change over extended time scales. Such studies could reveal developmental trajectories, periods of consolidation, or phases of heightened sensitivity to instruction that are not observable within a single academic year.

7.1.3 Unmodeled Task-Level Variation

Writing data were collected in authentic classroom settings, resulting in substantial variation in task topics, genres, instructional goals, and scaffolding. While this ecological validity strengthens the relevance of the findings, it introduces task-level variability that cannot be fully disentangled from student-level variability. In the absence of repeated or standardized prompts, it remains difficult to separate task-specific effects from within-student fluctuation, particularly for features that exhibited low or zero stability in RQ1.

Additionally, temporal distribution data for writing sessions across the academic year was not recorded, limiting our ability to assess whether uneven clustering of sessions could have introduced bias in ICC estimation. Task-level metadata, including genre classification and prompt type, was also not fully available at the time of analysis, constraining interpretation of school-level effects and task-driven variability. Future work will incorporate richer task annotation as labeling efforts are completed.

A related limitation concerns the inclusion of non-ELA writing tasks, such as lab reports and class notes, alongside ELA assignments. While this reflects the authentic range of classroom writing students engage in, it introduces additional heterogeneity that may affect certain feature families disproportionately. For instance, complexity features designed to capture syntactic elaboration may be less interpretable for highly formulaic or note-taking tasks.

Future research could adopt hybrid study designs that combine naturalistic classroom writing with repeated benchmark tasks, and examine whether stability patterns hold when analyses are restricted to ELA writing. Such designs would allow more direct estimation of test–retest reliability while preserving ecological validity. Additionally, richer annotation of task characteristics, such as genre, prompt complexity, revision expectations, and instructional supports, would enable more precise modeling of context-sensitive writing behaviors across subject areas.

7.1.4 Future Research Directions

Building on the findings of this study, several directions for future research are planned. First, we will integrate writing quality outcomes to model how stable and context-sensitive process features relate to writing development over time. Second, stability estimates from RQ1 can be leveraged to design process-aware educational tools, such as dashboards that emphasize meaningful deviations from a student's typical writing behavior rather than raw feature values.

Finally, future work will investigate the sources of stability and variability through richer contextual modeling and qualitative inquiry, and will extend the feature set to include linguistic, syntactic, and higher-level process indicators. Together, these efforts aim to advance a more nuanced understanding of writing processes as both persistent and adaptive, supporting longitudinal modeling and actionable educational data mining applications.

ABSTRACT

To advance Educational Data Mining (EDM) within strict privacy-protecting regulatory frameworks, researchers must develop methods that enable data-driven analysis while protecting sensitive student information. Synthetic data generation is one such approach, enabling the release of statistically generated samples instead of real student records; however, existing deep learning and parametric generators often distort marginal distributions and degrade under iterative regeneration, leading to distribution drift and progressive loss of distributional support that compromise reliability. In response, we introduce the Non-Parametric Gaussian Copula (NPGC), a plug-and-play synthesis method that replaces deep learning and parametric optimization with empirical statistical anchoring to preserve the observed marginal distributions while modeling dependencies through a copula framework. NPGC integrates Differential Privacy (DP) at both the marginal and correlation levels, supports heterogeneous variable types, and treats missing data as an explicit state to retain informative absence patterns. We evaluate NPGC against deep learning and parametric baselines on five benchmark datasets and demonstrate that it remains stable across multiple regeneration cycles and achieves competitive downstream performance at substantially lower computational cost. We further validate NPGC through deployment in a real-world online learning platform, demonstrating its practicality for privacy-preserving research.

Synthetic data generation, differential privacy, educational data, marginal distribution preservation, model collapse

1. INTRODUCTION

Educational Data Mining (EDM) and Learning Analytics (LA) rely on student-level records such as interaction logs, assessment outcomes, and contextual variables, governed by strict privacy and data-protection regulations. Even after removing direct identifiers, education datasets may remain disclosive because fine-grained behavioral traces and contextual variables enable re-identification or harm [24]. This constraint is evident in the field's open-science record: A reproducibility audit of LAK proceedings (11th–12th conferences) found that 5% of papers shared raw datasets and 2% reported data available "on request" [18]. A parallel audit of EDM proceedings (14th–15th conferences) found that 15% of papers used or shared open datasets, 5% reported availability "on request," and most provided no accessible pathway to datasets [17]. Together, these findings indicate a structural constraint on cumulative progress in EDM and LA: The data that power state-of-the-art models are often the least shareable, limiting reproducibility, benchmarking, and cross-institution comparison.

The impact of this constraint is increasing with the rapid uptake of generative AI (genAI), particularly large language models (LLMs) [51], which increases demand for high-quality student datasets, including open-ended responses, code, and dialogue. A recent systematic review of empirical LLM-in-education studies (Nov 2022–Mar 2025) documents rapid

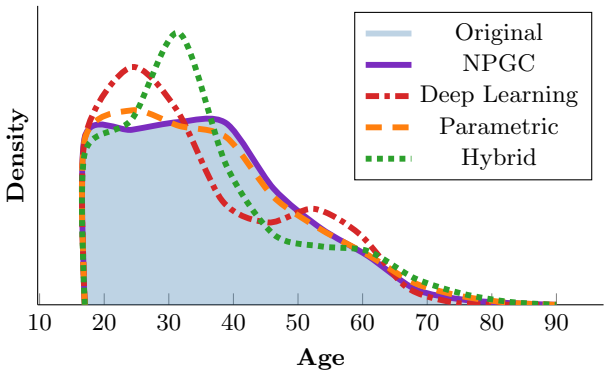

Figure 1: Marginal density of the *Age* variable in the Adult [2] dataset. The shaded region denotes the empirical density of the real data. Curves correspond to synthetic samples generated by a deep learning model, a Parametric Gaussian Copula (PGC), a Copula-GAN hybrid, and our proposed Non-Parametric Gaussian Copula (NPGC). Existing methods exhibit visible deviations from the empirical marginal, whereas NPGC aligns perfectly with the real distribution.

deployment while highlighting recurring privacy and governance challenges [40]. Many LLM-based learning supports (e.g., tutor-style feedback and hint generation) are validated on real student work and interaction traces that are difficult to release safely at scale due to re-identification risk [35]. The model-development pipeline introduces additional exposure: Fine-tuning and adaptation rely on sensitive datasets and admit privacy attacks (e.g., membership inference and data extraction), motivating stronger privacy-preserving practices [10]. This tension between data-hungry models and privacy-constrained records makes synthetic data generation compelling for EDM and LA, enabling method development and sharing while reducing reliance on protected student records and motivating the methodology proposed in this paper.

Synthetic data generation for tabular data (SDG-T) provides a practical approach for addressing this constraint. By combining statistical modeling with Differential Privacy (DP) [13] and established privacy evaluation protocols [15], SDG-T constructs artificial datasets that preserve statistical structure without exposing individual records. SDG-T enables privacy-compliant analysis and model development in educational settings. Unlike conventional deidentification, i.e., removing direct identifiers such as names and addresses, which offers no guarantees against reidentification through linkage with auxiliary data, DP is a formal framework that limits how much any single individual's record can influence released statistics, governed by a privacy parameter ϵ, where smaller values indicate stronger privacy. A useful property of DP is that any further processing of a DP output remains differentially private at the same ϵ.

Despite its promise, SDG-T faces a central technical challenge: preserving the empirical marginal distributions of heterogeneous variables. We refer to deviations between real and synthetic feature distributions as *marginal mismatch*. Educational attributes, such as test scores, attendance rates, or financial aid counts, rarely follow standard parametric families and often exhibit skewness, multi-modality, and discrete mass points.

Deep learning generators, including TVAE [36] and CTGAN [53], optimize joint objectives that prioritize inter-column dependencies, often causing systematic errors like mode collapse [25]. These models can distort individual marginals even when aggregate utility metrics appear competitive. Parametric approaches, such as the Gaussian Copula [44], assume predefined marginal distributions that may not reflect the real data shape. Hybrid methods, including Copula-GAN [34], apply Gaussianization before adversarial training, but still rely on fitted marginal models and do not guarantee exact empirical recovery.

As shown in Fig. 1, existing generators often distort individual feature marginals relative to the empirical data. Deep learning models lack explicit marginal constraints, whereas parametric approaches impose distributional forms that may not reflect the true distribution of the variables. In contrast, NPGC preserves empirical marginals through non-parametric anchoring. Marginal drift can bias downstream analysis; this example reflects behavior observed consistently across datasets in our experiments.

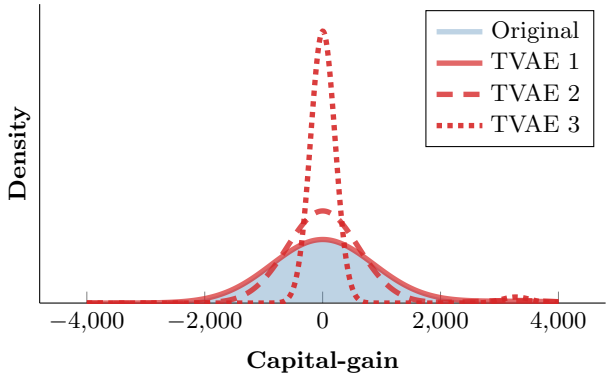

Figure 2: Marginal density of the *Capital-gain* variable in the Adult [2] dataset across three sequential regeneration iterations of a Tabular Variational Autoencoder (TVAE). The shaded region denotes the empirical density of the original data, and red curves (iterations 1–3) represent synthetic samples generated under repeated synthetic feedback. The progressive concentration of probability mass indicates variance collapse and loss of distributional support across iterations.

Marginal distortion is further amplified under iterative regeneration. Because synthetic data can be produced at scale [52], subsequent models may be trained on previously generated samples rather than on the original dataset [41]. We refer to this recursive setting as a Synthetic Feedback Loop (SFL). To quantify robustness under SFL, we define regeneration stability as the preservation of statistical structure across iterations. Under repeated regeneration, SFL can produce progressive variance shrinkage and loss of distributional support, consistent with *model collapse* [1].

We examine this SFL phenomenon in tabular synthesis. As shown in Fig. 2, unconstrained regeneration leads to systematic deviation from the original distribution across iterations. Such degradation is particularly consequential in educational datasets, where sub-representation of low-frequency groups can bias subgroup analysis and downstream prediction.

To address both marginal mismatch and regeneration instability, we introduce the Non-Parametric Gaussian Copula (NPGC). NPGC enforces exact empirical marginal preservation through non-parametric anchoring while modeling inter-variable dependencies in a Gaussian copula framework. NPGC supports continuous, integer, and categorical variables, and treats missing values as informative signals when estimating marginals and correlations. Beyond private synthesis, NPGC supports data augmentation, where empirical marginal anchoring ensures augmented samples preserve feature distributions, preventing statistical drift and erasure of rare subgroups.

NPGC integrates DP by injecting calibrated noise into both the marginal distributions and the correlation structure, providing formal privacy guarantees. By constraining synthetic generation to respect empirical marginals, NPGC mitigates variance degradation under SFL while maintaining competitive downstream utility and substantially lower computa-

tional cost than deep learning–based baselines. While NPGC improves marginal fidelity and regeneration stability, it models dependencies through a Gaussian copula on rank-transformed data. The Gaussian copula is parameterized solely by a correlation matrix and thus cannot represent interactions beyond linear rank correlation; as a result, complex nonlinear or higher-order dependencies may not be fully preserved.

We evaluate NPGC with respect to fidelity, privacy, regeneration stability, and downstream predictive utility, each formally defined in Section 4. Fidelity measures statistical agreement between real and synthetic data, privacy quantifies resistance to disclosure and inference attacks, and regeneration stability evaluates robustness under iterative synthesis.

Experiments are conducted on five datasets from the UCI Machine Learning Repository [11], a widely used benchmark collection of heterogeneous tabular datasets, including two education-focused datasets (*Student Dropout* [30], and *Student Performance* [6]). Figures 1 and 2 use the *Adult* [2] dataset due to its larger sample size, which enables clear visualization of marginal behavior and regeneration effects.

Across benchmarks, NPGC achieves higher fidelity and privacy scores than baseline methods while maintaining competitive utility and substantially lower computational cost. By enforcing empirical marginals, NPGC stabilizes regeneration under SFL and mitigates variance degradation.

We further evaluate NPGC on the OpenStax learning platform using engineer-generated test interaction logs from the platform's quality assurance system. The dataset exhibits severe categorical imbalance, a common characteristic of educational activity data. NPGC preserves empirical category proportions under this imbalance while satisfying privacy constraints. We demonstrate that the NPGC supports practical data sharing for instructional analytics without exposing individual-level records. We implement NPGC in Python as a synthesizer wrapper designed for straightforward integration into existing data workflows, enabling practical plug-and-play deployment.[1]

This paper is organized as follows. Section 2 reviews prior approaches to tabular data generation and related instability phenomena. Section 3 presents the formal formulation of NPGC. Section 4 describes the benchmark datasets and the evaluation protocols. Section 5 reports comparative results on fidelity, privacy, and regeneration stability. Section 6 details an applied case study on the OpenStax learning platform. Sections 7 and 8 discuss, conclude, and outline future directions.

2. RELATED WORK

Synthetic tabular data generation has long been studied as a mechanism for releasing useful data while controlling disclosure risk [37, 49]. In education, the tension between utility, fidelity, privacy, and validity constraints is particularly pronounced: Student-level datasets are high-dimensional and heterogeneous, combining continuous, integer/count, categorical, and ordinal variables within a single table, yet institutional and regulatory constraints often prevent broad sharing for benchmarking and reproducibility. Recent surveys and benchmark studies show that reported rankings of tabular generators can depend strongly on evaluation protocols, hyperparameter tuning effort, and available compute resources [19, 27, 23, 48]. These findings motivate synthesis methods that are not only competitive in utility but also stable, reproducible, and computationally accessible.

Following the requirement-oriented taxonomy of [49], we summarize representative model families and position our approach relative to their design trade-offs.

2.1 Deep Learning for Tabular Data

Deep generative models are widely used for tabular synthesis to capture complex cross-feature dependencies. GAN-based approaches such as TGAN [55], CTGAN [54], and TVAE [36], and CTAB-GAN/CTAB-GAN+ [57, 58] adapt the adversarial framework of [16] to mixed continuous and categorical data through conditional training and tailored normalization schemes. Deep learning models often achieve strong downstream predictive performance. However, because they optimize global or reconstruction objectives, marginal distributions are not explicitly constrained; univariate shapes can deviate from empirical distributions [25], particularly for skewed or multi-modal educational attributes (Fig. 1).

Diffusion- and score-based extensions, including TabDDPM [26], STaSy [22], CoDi [28], AutoDiff [50], FinDiff [39], and TabSyn [56], increase modeling flexibility through multi-step denoising objectives [45, 20]. LLM-based generators such as GReaT [4], built on Transformer architectures [51], provide flexible conditioning at the cost of substantial computational resources. Empirical studies further indicate that deep learning does not consistently outperform simpler approaches on tabular data and typically requires greater tuning effort [42, 23].

Given our objective of providing a lightweight, stable, and reproducible synthesizer for privacy-sensitive educational datasets, we restrict our deep learning baselines to representative GAN/VAE models (CTGAN and TVAE), enabling controlled comparison against a statistical alternative.

2.2 Parametric and Copula-Based Statistical Methods

Copulas provide a classical framework for modeling multivariate dependence by separating marginals from the joint structure under Sklar's theorem [44]. Gaussian and vine copulas are widely used in finance, marketing, survival analysis, and applied statistics [46, 9, 33, 7, 8, 21]. Their decoupled formulation enables efficient sampling and interpretability, motivating synthetic tabular systems such as the Gaussian-copula model implemented in the Synthetic Data Vault (SDV) [34], a Python library for generating synthetic tabular data, and related copula-based generators for complex data [3].

Most copula-based synthesizers assume parametric marginal

[1]The synthetic data generation toolkit is available: `https://github.com/gdiaz95/Synthetic_data_generation`

families. When educational attributes are skewed, discrete, or multi-modal, such assumptions can introduce systematic distortion. Differentially private extensions such as DPCopula [29] inject calibrated noise into marginal and correlation estimates to satisfy formal DP guarantees, but privacy noise may exacerbate misspecification effects. Nonparametric copula generators based on empirical CDFs relax distributional assumptions [38], yet they do not explicitly address DP accounting, regeneration stability, or reproducible low-overhead benchmarking in privacy-restricted educational settings.

NPGC retains the copula decomposition while replacing parametric marginals with privatized empirical anchors and enforcing positive semi-definite correction of the noisy correlation matrix. This design prioritizes exact marginal fidelity, computational efficiency, and reproducibility under constrained compute, positioning NPGC as a lightweight statistical alternative rather than a high-capacity hybrid or deep generator.

2.3 Recursive Training and Synthetic Feedback Effects

Researchers increasingly reuse synthetically generated data for downstream training, distillation, and iterative regeneration. When models train on data generated by earlier models, distributional drift can arise. Recent work documents instability under recursive self-training, including Model Autophagic Disorder (MAD) [1], model collapse [41], degradation of diversity when scaling with synthetic data alone [14], and progressive loss of variance and tail behavior in large models trained on recursively generated corpora [41]. In GAN settings, researchers attribute such behavior to the concentration of probability mass on limited modes and propose mitigation strategies such as VEEGAN [47]. Related analyses in LLM fine-tuning show that recursive adaptation can amplify distributional bias [31].

Although this literature focuses primarily on vision and language models, the underlying mechanism, accumulation of approximation error under repeated self-consumption, extends directly to tabular synthesis. In tabular data, even small marginal distortions can compound across generations, attenuating rare categories or low-frequency subgroups. In educational settings, such drift is particularly consequential because subgroup underrepresentation may bias downstream analytics, fairness assessments, and policy decisions.

To the best of our knowledge, model collapse and regeneration stability have not been systematically analyzed in privacy-sensitive tabular synthesis. We therefore introduce an explicit empirical evaluation of synthetic feedback effects in tabular data. In Section 5, we examine how marginal preservation influences recursive stability and whether constraining marginals mitigates variance shrinkage under synthetic feedback.

3. NON-PARAMETRIC GAUSSIAN COPULA (NPGC)

We formulate NPGC as a three-stage generative process grounded in Sklar's Theorem [44], which decomposes a joint distribution into univariate marginal distributions and a copula-based dependency structure. To provide formal privacy guarantees, differential privacy (DP) [13] is incorporated directly into both marginal estimation and correlation modeling. The procedure is defined as follows:

3.1 Marginal Transformation: $X \to Z$

Intuitively, this step reorders each variable into a common Gaussian scale while storing its observed distribution, allowing dependencies to be modeled separately from marginal shapes. NPGC maps the original data matrix $X \in \mathbb{R}^{n\times p}$ into a latent Gaussian space $Z \in \mathbb{R}^{n\times p}$ column-wise, where n denotes the number of records and p the number of features. Privacy is enforced during marginal estimation prior to Gaussian projection. For each feature column X_j ($j = 1, \ldots, p$), the transformation proceeds in two steps:

1. Mapping of X_j to a variable $U_j \in (0, 1)$ via a column-specific empirical probability integral transform; under consistency of $\widehat{F}_j$, $U_j \Rightarrow \mathcal{U}(0, 1)$.
2. Projection to the standard Gaussian space via $Z_j = \Phi^{-1}(U_j)$, where Φ denotes the cumulative distribution function of the standard normal distribution.

For continuous variables, we map observed values to the unit interval using a histogram-based estimate of the marginal CDF. Let $\widehat{F}_j$ denote the empirical CDF constructed from the non-missing entries of column j. We set $U_j = \widehat{F}_j(X_j)$ using linear interpolation, so that $U_j \in (0, 1)$.

For integer-valued variables with empirical probability mass function p_j and CDF $\widehat{F}_j$, we apply dequantization $U_j = \widehat{F}_j(X_j) - r\, p_j(X_j)$ with $r \sim \mathcal{U}(0, 1)$, which distributes probability mass uniformly over $(\widehat{F}_j(x^-), \widehat{F}_j(x)]$ for each observed value x, where x^- denotes the immediate predecessor of x in the ordered discrete support.

Categorical variables are treated analogously by estimating empirical category probabilities and sampling uniformly within each category's CDF interval. This embeds continuous, integer, and categorical variables into a common continuous domain $(0, 1)$.

Let f_{nan} denote the empirical fraction of missing values in column j. Observed numeric values are scaled to occupy $(0, 1 - f_{\text{nan}})$, while the upper interval $(1 - f_{\text{nan}}, 1)$ is reserved for missingness. This produces a disjoint partition of $(0, 1)$ in which observed variability and missingness are encoded separately. This representation also preserves correlations between missingness and observed variables. As a result, missingness patterns can be reproduced when they are reflected in the data (e.g., missing values occurring more frequently within specific subgroups). However, if missingness depends on unobserved factors, these dependencies cannot be fully recovered, since the copula captures only associations among observed variables. After uniformization, we apply the Gaussian projection $Z_j = \Phi^{-1}(U_j)$, where Φ is the standard normal CDF, yielding latent variables with approximately standard normal marginals for correlation estimation.

Concretely, DP is enforced by adding calibrated random noise to the statistics NPGC fits (the histogram bin counts

for each marginal and entries of the correlation matrix), scaled according to the sensitivity of each statistic and the privacy parameter ϵ. NPGC adds DP noise to two quantities, namely, the marginals and the correlation matrix, so we split the ϵ between them. This split is called a *privacy budget* $\epsilon = \epsilon_m + \epsilon_c$ with $\epsilon_m = \epsilon_c = \epsilon/2$, where ϵ_m is applied to marginal estimation and ϵ_c to correlation estimation. Marginal distributions are privatized using the Laplace mechanism under ϵ_m-differential privacy per column, with $\epsilon = 1$ by default and configurable by the user. For histogram bin counts h_k, we construct $\tilde{h}_k = \max(0, h_k + \eta_k)$ with $\eta_k \sim \text{Lap}(1/\epsilon_m)$. For categorical or integer counts c_ℓ, we construct $\tilde{c}_\ell = \max(0, c_\ell + \eta_\ell)$ with $\eta_\ell \sim \text{Lap}(1/\epsilon_m)$. The empirical CDF $\widehat{F}_j$ is then formed from the normalized perturbed counts and stored for inverse sampling (Section 3.3). Under sequential composition across all p columns, the total privacy cost of the marginal step is $p \cdot \epsilon_m$.

The resulting matrix $Z \in \mathbb{R}^{n \times p}$ has standard normal marginals across columns. Specifically, let Z_j denote the j-th column of Z. Then $Z_j \sim \mathcal{N}(0, 1)$, and the columns are suitable for correlation estimation in the latent Gaussian space.

3.2 Correlation and Gaussian Sampling

In simple terms, this step captures how variables co-vary after removing their individual distributions, enabling joint dependence to be reproduced independently of individual form. Once the data is transformed into the Gaussian space Z, we estimate and replicate the dependency structure. We compute the empirical correlation matrix $\widehat{R} = \frac{1}{n-1} Z^\top Z$. The matrix is privatized by adding symmetric Laplace noise to each entry. Since $Z_{ij} = \Phi^{-1}(\widehat{F}_j(X_{ij}))$ and the empirical CDF maps observations to ranks, the maximum value any entry of Z can take is $\Phi^{-1}(n/(n+1))$, yielding a data-independent per-entry sensitivity of $[\Phi^{-1}(n/(n+1))]^2/(n-1)$. Noise is added with scale $b = [\Phi^{-1}(n/(n+1))]^2/((n-1)\epsilon_c)$ per entry, so that each entry satisfies ϵ_c-differential privacy. Under sequential composition across all $p(p-1)$ off-diagonal entries, the total privacy cost of the correlation step is $p(p-1)\cdot\epsilon_c$. Let $\tilde{R}$ denote the noisy matrix. To enforce positive semi-definiteness, we compute the eigen-decomposition $\tilde{R} = V \Lambda V^\top$ and replace Λ with $\Lambda^+ = \text{diag}(\max(\lambda_k, \delta))$, where we use $\delta = 10^{-8}$ in practice. The matrix is then reconstructed as $\widehat{R} = V \Lambda^+ V^\top$ and normalized to have a unit diagonal. The resulting $\widehat{R}$ is stored for subsequent sampling.

We generate $Z_{\text{iid}} \in \mathbb{R}^{m \times p}$, where m denotes the number of generated samples, with rows sampled independently as $\mathcal{N}(0, I_p)$. Let $\widehat{R} = LL^\top$ denote the Cholesky factorization of the learned correlation matrix. Correlated samples are obtained via $Z_{\text{syn}} = Z_{\text{iid}} L^\top$. Each row of Z_{syn} then follows $\mathcal{N}(0, \widehat{R})$, yielding a synthetic Gaussian matrix that preserves the learned dependency structure.

3.3 Marginal Reconstruction: $Z_{\text{syn}} \to X_{\text{syn}}$

This step converts the synthetic data back into the original format of the dataset using the empirical marginal anchors, preserving the original distributions. Since sampling depends only on the privatized marginals $\widehat{F}_j$ and correlation matrix $\widehat{R}$, the inverse stage is a post-processing operation. We now map the Gaussian samples Z_{syn} back to the original feature space to obtain X_{syn} by reversing the forward transformation:

1. Map to uniform domain via the standard normal CDF: $U_{\text{syn},j} = \Phi(Z_{\text{syn},j})$.
2. Apply inverse empirical CDF, $X_{\text{syn},j} = \widehat{F}_j^{-1}(U_{\text{syn},j})$, using interpolation for continuous variables and bin assignment for discrete types.

The generative process yields $X_{\text{syn}} \in \mathbb{R}^{m \times p}$. Marginals are generated using empirical anchors stored during fitting: sorted empirical values for numeric columns and (noisy) category masses for categorical columns, applied through inverse empirical CDF sampling. In contrast to standard Gaussian copula models that assume parametric marginal families, NPGC relies directly on empirical (and privatized) marginal distributions while modeling dependencies solely through the Gaussian copula correlation structure.

To simplify usage, NPGC is implemented as a synthesizer class following a standard fit–sample paradigm. As shown in Listing 1, the user fits the model to a tabular dataset. The fit step estimates the empirical marginal distributions and the Gaussian copula correlation matrix. After fitting, the model can generate synthetic samples of arbitrary size, and the trained instance can be saved to or loaded from disk for reproducible generation. In practice, this follows a straightforward workflow: fit the model to real data, then generate synthetic samples from the learned distributions.

Listing 1: Example usage of the Non-Parametric Gaussian Copula (NPGC) synthesizer.

```
# Instantiate the NPGC synthesizer
synthesizer = NPGC()

# Fit the model to the original dataset (pandas
    DataFrame input)
synthesizer.fit(original_dataframe)

# Alternatively, load a previously trained model
synthesizer.load("models/synthetic_model.pkl")

# Generate synthetic samples (returned as a
    pandas DataFrame)
synthetic_data = synthesizer.sample(num_rows
    =1000)

# Save the fitted model for future reuse
synthesizer.save("models/synthetic_model.pkl")
```

An overview of the NPGC fit and sample procedures is shown in Fig. 3. The model consists of two components: privatized empirical marginals and a Gaussian copula correlation matrix. The fit phase estimates these quantities in a latent Gaussian space, and the sample phase generates correlated Gaussian draws followed by inverse marginal reconstruction to produce synthetic data. Details of the computational complexity for the fit and sample procedures are provided in Appendix B.1.

4. EXPERIMENTAL SETUP

The datasets reflect heterogeneous tabular structure, varying in sample size from $n = 649$ to $n > 45{,}000$ and in dimensionality from $p = 4$ to $p = 36$, with mixtures of continuous,

Table 1: Benchmark datasets used for evaluation, showing the number of instances and features for each dataset.

Dataset	Instances (n)	Features (p)
Adult [2]	48,842	14
Balance Scale [43]	625	4
Nursery [32]	12,960	8
Student Dropout [30]	4,424	36
Student Performance [6]	649	33

discrete, and categorical variables and missing values in several cases. We do not impose a theoretical minimum sample size. Robustness to dataset size is assessed empirically across benchmarks ranging from $n = 625$ to $n > 45{,}000$ (Table 1). NPGC maintains stable performance across this range, including the smallest dataset ($n = 649$), without dataset-specific tuning. For each dataset, we generate a synthetic dataset of size equal to the training partition ($m = 0.8n$). Each dataset is split once into fixed 80/20 train–holdout partitions, following standard practice, for fidelity and privacy evaluation. For utility, a separate 70/30 split is used for Train-on-Synthetic, Test-on-Real (TSTR) evaluation, as downstream classifier evaluation benefits from a larger test partition; both partitions use a predefined random seed. Synthetic samples are generated from the training split only. The holdout set is never used for model fitting and remains fixed across regeneration iterations.

We evaluate NPGC against four baseline models implemented using the Synthetic Data Vault (SDV) single-table synthesizers [34], selected to represent the main classes in tabular data synthesis: parametric copula models (PGC) [44], deep generative models (CTGAN, TVAE) [54, 53], and hybrid approaches (Copula-GAN). Baselines provide a consistent basis for comparison within the SDV framework, covering the main modeling paradigms used in tabular synthesis and enabling evaluation across parametric, deep learning, and hybrid approaches. Future work may evaluate NPGC against more recent tabular synthesis methods. Experiments are conducted on the benchmark datasets summarized in Table 1, obtained from the UCI Machine Learning Repository [11].

We evaluate synthetic data quality using three standard criteria,fidelity, utility, and privacy, following established practice [49]. In addition, we introduce a regeneration stability protocol that measures robustness under iterative synthetic feedback.

Fidelity measures agreement between the statistical structure of real and synthetic data. It is quantified using the SD Metrics single-table Quality Report [34], summarized by the Overall Score, defined as the arithmetic mean of the report's univariate and bivariate components: Column Shapes (univariate distribution agreement, including Kolmogorov–Smirnov comparisons for numerical variables) and Column Pair Trends (pairwise relationship preservation). These scores lie in $[0, 1]$, with 1 indicating perfect agreement under the SDMetrics definitions.

Privacy refers to protecting sensitive information in the original dataset and preventing the synthetic output from enabling re-identification attacks (e.g., linkage, inference, or membership attacks). In this work, privacy is evaluated using Discriminator AUC and Distance to Closest Record (DCR) Share [34]. Discriminator AUC is computed by training a binary classifier solely for evaluation to distinguish real from synthetic samples and measuring the area under the receiver operating characteristic curve. DCR Share quantifies proximity between synthetic and real records based on nearest-neighbor distances. Both metrics are bounded in $[0, 1]$, and values closer to 0.5 indicate lower separability and reduced memorization risk.

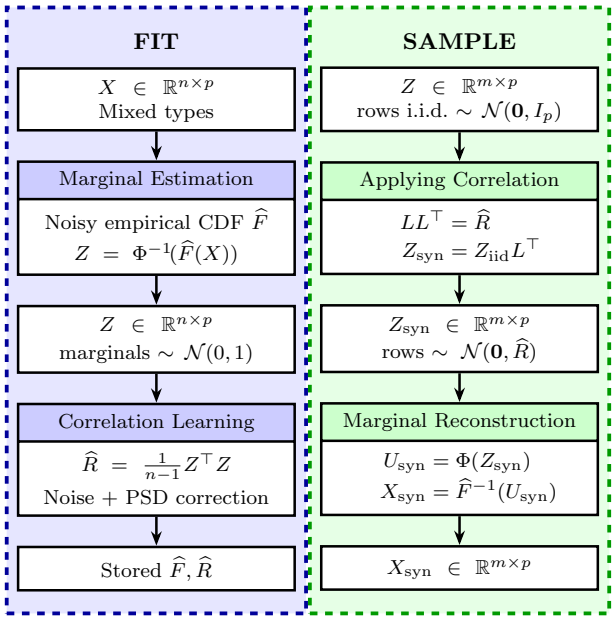

Figure 3: Overview of NPGC. FIT: Empirical marginal estimation via empirical Cumulative Distribution Functions (CDFs) with Gaussian projection, followed by correlation estimation $\widehat{R}$ with positive semi-definite (PSD) correction; the collection of marginals $\{\widehat{F}_j\}_{j=1}^{p}$, where p denotes the number of features (shown as $\widehat{F}$ in the figure for clarity), and $\widehat{R}$ are stored. SAMPLE: Independent Gaussian samples are correlated using Cholesky factorization $LL^\top$ of $\widehat{R}$ and mapped back through inverse empirical CDF reconstruction.

Utility refers to how fit for use the synthetic dataset is for the intended analytic task. In this work, utility is evaluated using the Train-on-Synthetic, Test-on-Real (TSTR) protocol together with runtime measurements. An XGBoost classifier [5] (fixed random seed, default hyperparameters) is trained on synthetic data and evaluated on real data using classification accuracy. We select XGBOOST as a baseline for TSTR due to its strong performance, robustness to heterogeneous feature types, and widespread use in educational data mining. Future work may evaluate utility across a broader set of predictive models. Accuracy is bounded in $[0, 1]$, with higher values indicating better predictive performance. Performance is compared to a classifier trained on real data under the same split, and relative degradation (Accuracy Drop) is reported. Training time denotes synthesizer fitting time, and evaluation time denotes synthetic sample

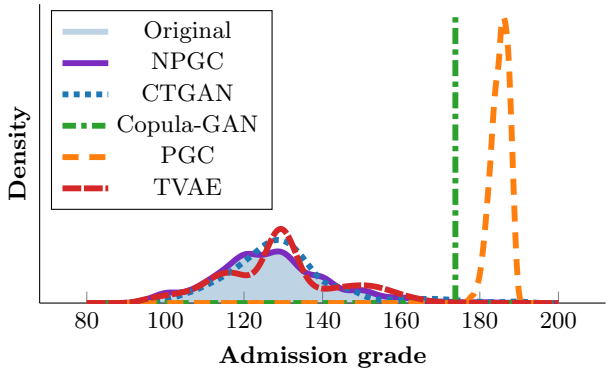

Figure 4: Marginal density of the Admission grade variable in the Student Dropout Success [30] dataset. The shaded region denotes the empirical density of the real data. Curves correspond to TGAN, TVAE, PGC, Copula-GAN, and the proposed NPGC. Deep learning and parametric baselines distort the marginal shape, while NPGC preserves it through empirical anchoring.

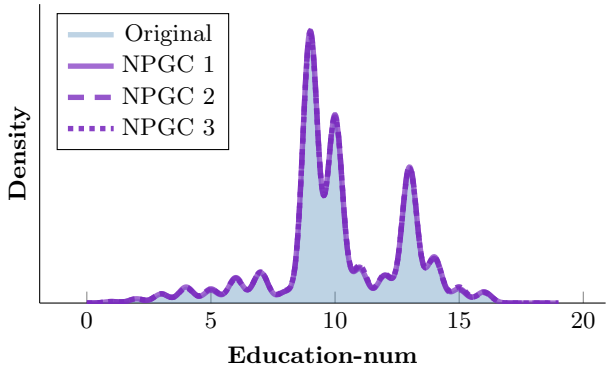

Figure 5: Marginal density of the *Education-num* variable in the Adult [2] dataset across three sequential regeneration iterations of NPGC. The shaded region denotes the empirical density of the original data, and purple curves (iterations 1–3) represent synthetic samples generated under repeated regeneration. The overlap across iterations demonstrates stability of the marginal distribution.

generation time.

Regeneration stability measures preservation of fidelity under repeated Synthetic Feedback Loop (SFL) iterations. It is evaluated using a 10-step synthetic feedback protocol on the Adult dataset [2]. At each iteration, the model is reinitialized and retrained on the synthetic dataset generated at the previous generation. Let $S^{(k)}$ denote the synthetic dataset generated at iteration k under SFL. Regeneration stability is defined as the preservation of the Overall Score between $S^{(k)}$ and the original real dataset across $k = 1, \ldots, 10$.

5. RESULTS

We evaluate NPGC against four baseline models across the five benchmark datasets described in Section 4. Results are reported for fidelity, utility, privacy, and regeneration stability and are averaged across all datasets (one aggregate score per dataset).

5.1 Fidelity

Fidelity measures how closely the synthetic data matches the statistical structure of the real data. In practice, higher fidelity indicates that summary statistics and distributions remain consistent between real and synthetic datasets. As shown in Table 2, NPGC achieves the highest Overall Score (0.962), as well as the highest Column Shapes score (0.985) and Column Pair Trends score (0.939). These results indicate that NPGC consistently outperforms all baselines in fidelity across both univariate and pairwise correlation preservation.

Figure 4 compares the marginal distribution of the *Admission grade* variable in the Student Dropout Success [30] dataset. The Copula-GAN collapses the distribution into a narrow spike near $x \approx 177.8$, indicating incorrect assumptions. PGC produces a unimodal approximation that does not capture the non-standard structure of the real data. NPGC consistently reproduces the empirical marginal.

5.2 Privacy

Privacy measures the extent to which individual records from the real dataset are protected. In practice, stronger privacy indicates a lower risk of distinguishing or linking synthetic samples to real individuals. As shown in Table 3, NPGC achieves the lowest Discriminator AUC (0.801) and DCR Share (0.527). Since values closer to 0.5 indicate lower separability and memorization, NPGC provides the strongest privacy performance among all methods.

5.3 Utility

Utility measures how useful the synthetic data is for downstream tasks. In practice, this reflects whether models trained on synthetic data behave similarly when applied to real data. Tables 4 and 5 show that TVAE attains the lowest accuracy drop (8.66%), while NPGC achieves a competitive drop of 16.99%, outperforming CTGAN and Copula-GAN and providing stronger privacy guarantees than TVAE.

Training times differ substantially: CTGAN and Copula-GAN exceed 790 seconds, TVAE requires 268 seconds, PGC 11.86 seconds, and NPGC 0.65 seconds. Sampling times are below 1.2 seconds for all methods. NPGC, as a non-deep-learning model, achieves orders-of-magnitude speedups over deep learning baselines and remains substantially faster than the PGC baseline.

Table 2: Average fidelity metrics across datasets. Overall Score reflects univariate (Column Shapes) and bivariate (Pair Trends) agreement between synthetic and real data. NPGC attains the highest fidelity across all metrics.

Model	Overall Score	Column Shapes	Pair Trends
NPGC	**0.962**	**0.985**	**0.939**
CTGAN	0.895	0.918	0.872
Copula-GAN	0.888	0.914	0.863
PGC	0.897	0.913	0.881
TVAE	0.832	0.883	0.781

Table 3: **Average privacy metrics across datasets. Lower values indicate reduced real–synthetic separability and lower memorization risk. NPGC achieves the strongest privacy performance.**

Model	Discriminator AUC	DCR Share
NPGC	**0.801**	**0.527**
CTGAN	0.853	0.567
Copula-GAN	0.871	0.558
PGC	0.850	0.549
TVAE	0.910	0.545

5.4 Regeneration Stability

Regeneration stability measures how well the synthetic data preserves its fidelity under repeated generation. In practice, this indicates whether the data maintains its variability and distribution across iterations. Regeneration stability is evaluated only on the Adult [2] dataset using the 10-step synthetic feedback protocol described in Section 4. As shown in Fig. 5, we observe the marginal distribution of the *Education-num* variable across successive NPGC iterations. NPGC correctly preserves the multi-modal empirical marginal distribution across iterations with minimal drift by construction, illustrating the absence of model collapse under repeated regeneration.

This marginal stability is reflected in the aggregate fidelity metric. As shown in Fig. 6, NPGC Overall Score decreases from 96.43% at iteration 1 to 95.27% at iteration 10 (1.16 percentage points). Copula-GAN decreases from 88.93% to 49.25%, CTGAN from 86.31% to 57.38%, TVAE from 89.33% to 65.56%, and PGC from 84.53% to 78.69%. These results show that NPGC maintains marginal and bivariate structure (as captured by the Overall Score) under repeated regeneration, while alternative methods exhibit substantial degradation.

6. EDUCATIONAL RESEARCH APPLICATION

We evaluate NPGC in an applied setting using engineer-generated test interaction logs from Assignable, the OpenStax homework platform that records student activity using the Experience API (xAPI) standard. The platform organizes student work hierarchically: each *assignment* contains several *activities*, and *assessment* activities contain individual *assessment-questions*. We analyze the activity layer only.

Table 4: **Average Train-on-Synthetic, Test-on-Real (TSTR) utility metrics across datasets using XGBoost. Synthetic Score denotes classification accuracy when training on synthetic data and testing on real data, and Accuracy Drop measures the relative decrease compared to training on real data. NPGC achieves the second-highest utility.**

Model	Synthetic Score	Accuracy Drop (%)
NPGC	**0.739**	**16.99**
CTGAN	0.619	25.73
Copula-GAN	0.647	22.80
PGC	0.675	17.04
TVAE	0.797	8.66

Table 5: **Average computational runtimes across datasets. Train Time denotes model fitting time, and Eval Time denotes sampling and evaluation time. NPGC achieves the lowest training time.**

Model	Train Time (s)	Eval Time (s)
NPGC	**0.650**	**1.19**
CTGAN	821.01	0.68
Copula-GAN	791.90	0.75
PGC	11.860	1.03
TVAE	268.46	0.34

Each Assessment is therefore counted as a single event, regardless of how many questions it contains. This yields 1,509 test interactions spanning four activity types: Reading, Assessment, Ancillary, and AI Feature (see Appendix A for definitions).

The empirical distribution is severely imbalanced: Assessment events account for 72.1% of records, Reading for 26.0%, Ancillary for 1.2%, and AI Feature for 0.7%. Such an imbalance is characteristic of educational interaction data, where dominant activity types vastly outnumber emerging or supplementary ones. Standard synthesis methods often collapse low-frequency categories under this regime, precisely the ones most relevant for studying new or rare student behaviors. We apply NPGC to generate 1,982 augmented synthetic records.

Figure 7 compares activity-type proportions between the test and synthetic datasets. NPGC preserves all four proportions to within roughly one percentage point, including AI Feature at 0.81% in the synthetic data versus 0.73% in the test data. The 11 test AI-Feature events are reflected as 16 synthetic events at matched relative frequency, demonstrating that empirical anchoring preserves rare-class structure even under aggressive class imbalance.

7. DISCUSSION

Our results carry several implications for synthetic data practice in educational research. We organize this discussion around three themes: what NPGC's marginal preservation means for analytic validity, what its limitations imply for specific research designs, and what directions would most benefit the EDM community.

Safeguarding Rare Educational Signals. When synthesizers smooth multi-modal distributions or collapse low-frequency categories, as Copula-GAN and CTGAN did across benchmarks, the distortion is not evenly distributed. Rare subgroups are disproportionately affected: sparsely observed demographic categories, low-frequency event types, and tail behaviors are attenuated first. In educational datasets, these are often the populations of greatest analytic interest: underrepresented students, rare help-seeking behaviors, or atypical learning trajectories. NPGC's empirical anchoring preserves these distributional features by construction, reducing the risk that synthetic data silently erases the students/researchers who most need to study. Our case study (Section 6) illustrates this concretely: NPGC maintained the categorical proportions of a severely imbalanced activity-type distribution, including AI-feature events occurring in

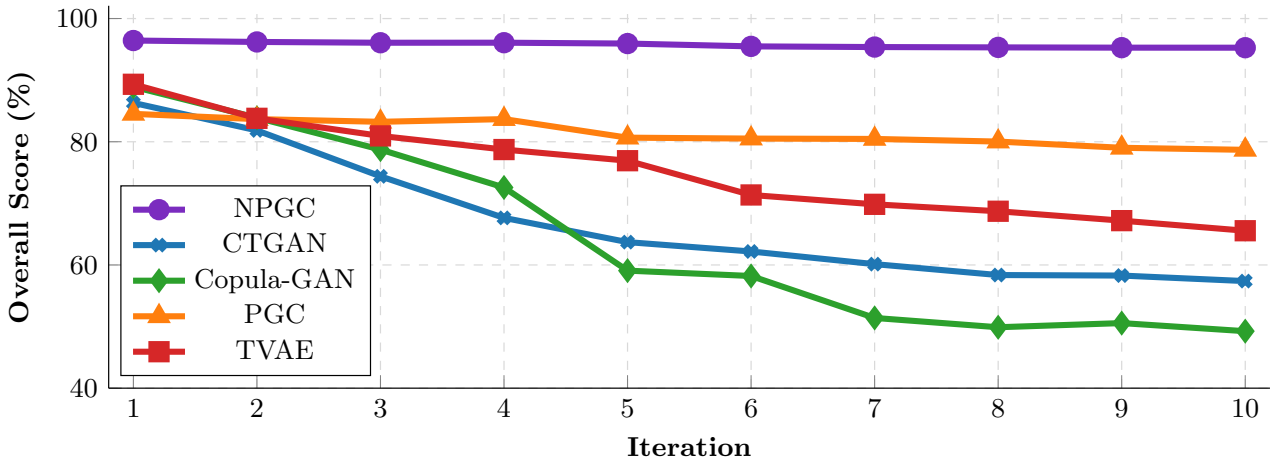

Figure 6: Overall Score (%) across 10 synthetic regeneration iterations on the Adult [2] dataset. The Overall Score aggregates univariate and bivariate distributional agreement between synthetic and real data. Curves correspond to CTGAN, Copula-GAN, PGC, TVAE, and NPGC.

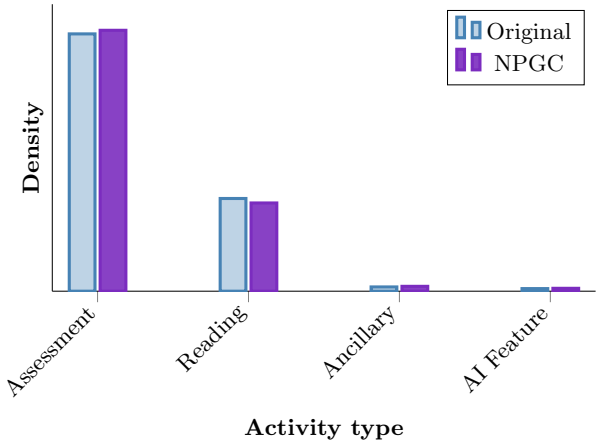

Figure 7: Proportion of activity types in the test and synthetic interaction dataset. The shaded bars represent empirical proportions from 1,509 test interaction records from the OpenStax platform. Synthetic proportions from 1,982 samples generated with NPGC closely match the empirical distribution across the four activity types, including low-frequency categories such as Ancillary and AI Feature. NPGC illustrates stable marginal preservation under deployment.

fewer than 1% of records.

The utility-fidelity tradeoff. NPGC achieves the highest fidelity but not the highest downstream classification accuracy; TVAE's accuracy drop (8.66%) is lower than NPGC's (16.99%). This gap likely reflects a fundamental tension: strict marginal anchoring constrains the joint distribution in ways that can sacrifice cross-feature predictive signal, particularly nonlinear interactions that deep generators capture through flexible function approximation. However, for many EDM use cases such as population characterization, distributional auditing, subgroup representation analysis, and descriptive reporting, marginal fidelity matters more than predictive utility. These differences have direct implications for common EDM tasks. In descriptive analyses, higher fidelity means that distributions of variables such as grades, activity counts, or demographic proportions remain consistent, so reported statistics do not change when using synthetic data. In predictive settings, comparable TSTR performance means that models trained on synthetic data behave similarly when evaluated on real data. For tasks such as dropout prediction or early warning systems, this reduces the risk that model outputs or intervention thresholds shift due to artifacts introduced during synthesis. Researchers should select their synthesizer based on their analytic objective.

Limitations and scope conditions. The Gaussian copula captures linear dependence structure in the latent space. Educational data frequently exhibits threshold effects, ceiling and floor artifacts, and nonlinear interactions (e.g., between prior knowledge and intervention response) that this assumption may not preserve. Additionally, our regeneration stability analysis was conducted on a single dataset; whether these properties generalize to high-cardinality educational features (e.g., course IDs or learning objective codes) remains an open question.

8. FUTURE DIRECTIONS

The most impactful extensions would address structures common in educational research: longitudinal panel data with temporal dependencies, multi-table relational schemas (students × courses × assessments), and conditional distributions relevant to causal inference in platform A/B experiments. Integrating flexible dependency models, such as vine copulas [8] or neural spline flows [12], while retaining empirical marginal anchoring could extend NPGC's applicability to these richer data structures without sacrificing its core marginal stability and reproducibility guarantees. Future work may also provide a more precise characterization of the dependency structures captured by the model, evaluate NPGC against more recent tabular synthesizers, and assess utility across a broader range of predictive models.

APPENDIX

A. OPENSTAX ONLINE INSTRUCTIONAL SYSTEM

The OpenStax platform delivers digital instructional content and assessments to middle-school and post-secondary learners, recording fine-grained student interactions as time-stamped Experience API (xAPI) statements.

This paper uses full xAPI logs of example data generated during quality assurance tests of the system containing 7,506 records at three levels: *assignment* (the top-level container), *activity* (what the student engages with inside an assignment), and *assessment-question* (an individual question inside an assessment). We analyze the activity level only, yielding 1,509 records across four *activity_type* categories: **Reading** (`reading`), interaction with instructional content such as textbook pages; **Assessment** (`assessment`), initiation of a practice or formative evaluation; **Ancillary** (`ancillary`), access to supplemental materials such as videos or external references; and **AI Feature** (`promptly:preset`), an AI chatbot feature currently under development. Each Assessment is counted as a single event; the questions inside it are not counted separately. The empirical distribution is highly imbalanced. Assessment accounts for ∼72% of records and AI-feature for under 1%, which poses challenges for generative methods that rely on parametric density assumptions or adversarial training.

Using the dataset's training split, we apply NPGC to generate 1,982 synthetic interaction records: 1,449 Assessment, 490 Reading, 27 Ancillary, and 16 AI-feature events, with proportional agreement to the original distribution and preservation of both dominant and low-frequency categories. Because NPGC operates on an aggregated tabular structure rather than reproducing individual-level sequences, the released synthetic data preserves categorical frequency structure while mitigating identity disclosure risk, supporting release for educational research under privacy constraints.

B. BASELINE HYPERPARAMETERS

All baseline models were implemented using the SDV single-table synthesizers. Unless otherwise specified, default SDV hyperparameters were used without additional tuning.

Parametric Gaussian Copula (PGC) models each numeric column using a specified parametric family and couples variables through a Gaussian copula correlation structure. The settings below indicate the default numeric marginal family and two post-processing constraints: whether generated values are clipped to the observed range and whether numeric outputs are rounded to match discrete-valued columns.

Copula-GAN applies a copula-based transformation and then trains a GAN to model dependencies in the transformed space. The hyperparameters below define the training budget (epochs, batch size), representation size (embedding dimension), network capacity (hidden layer sizes), optimizer step sizes (learning rates), discriminator update policy (steps), and the PAC setting (number of samples packed per discriminator input). The last two options enforce range clipping and rounding during post-processing to better match the original data domain.

Table 6: Parametric Gaussian Copula (PGC) Hyperparameters

Parameter	Value
Default numerical distribution	beta
Enforce min/max values	True
Enforce rounding	True

Table 7: Copula-GAN Hyperparameters

Discriminator hidden dimensions	(256, 256)
Generator learning rate	2×10^{-4}
Discriminator learning rate	2×10^{-4}
Discriminator steps	1
PAC	10
Enforce min/max values	True
Enforce rounding	True

CTGAN is a conditional GAN designed for mixed continuous and categorical tabular data. The hyperparameters below specify the training budget (epochs, batch size), embedding size for conditional vectors and categorical representations, generator/discriminator capacity (hidden dimensions), optimizer step sizes (learning rates), discriminator update policy (steps per generator update), and PAC packing. As above, min/max enforcement clips generated values to the observed range and rounding enforces discrete-valued outputs where applicable.

TVAE is a variational autoencoder for tabular data. The hyperparameters below specify the training budget (epochs), latent/embedding size, encoder (compression) and decoder (decompression) layer widths, the strength of L2 regularization, and the loss weighting factor used in SDV's implementation. Min/max enforcement clips outputs to the observed range, and rounding enforces discrete-valued outputs where

applicable.

NPGC is a nonparametric Gaussian copula synthesizer. The entries below summarize the privacy level used in experiments (the DP budget ϵ) and the modeling choices: no neural optimization, empirical (nonparametric) marginal anchoring, and dependence captured through a Gaussian copula correlation matrix.

B.1 Computational Complexity

Let n denote the number of rows in the training data and p the number of columns. For sampling, let m denote the number of generated rows. The computational cost of the non-parametric Gaussian copula synthesizer can be separated into the fitting stage and the sampling stage.

Fitting complexity. The algorithm learns the marginal distributions for each column and then estimates the latent Gaussian correlation matrix. For each of the p columns, the marginal-learning step requires sorting or equivalent ranking/uniqueness operations on up to n observations, yielding a cost of order $O(n \log n)$ per column. Across all columns, this contributes $O(pn \log n)$. After transforming the data into the latent Gaussian space, the empirical correlation matrix is computed from a matrix of size $n \times p$, which costs $O(np^2)$. When differential privacy is enabled, the noisy correlation matrix is projected onto the cone of valid correlation matrices through an eigen-decomposition, which costs $O(p^3)$. Therefore, the overall complexity of `fit()` is

$$O\big(pn \log n + np^2 + p^3\big)$$

when privacy is enabled, and $O\big(pn \log n + np^2\big)$ when the correlation-repair step is skipped.

Sampling complexity. The algorithm first generates an independent Gaussian matrix of size $m \times p$, which costs $O(mp)$. It then applies the learned correlation structure using a Cholesky factorization of the $p \times p$ correlation matrix. Computing the factorization costs $O(p^3)$, and multiplying the sampled Gaussian matrix by the Cholesky factor $O(mp^2)$. Finally, each column is transformed back through its inverse empirical CDF. For continuous and categorical variables, this step is typically linear in the number of generated samples, contributing approximately $O(mp)$ overall. Hence, the typical complexity of `sample()` is

$$O\big(mp^2 + p^3\big)\,.$$

There is, however, an important exception for integer-valued variables when minimum and maximum values are enforced. In that case, the inverse transformation compares each generated value against all unique observed integer levels. If a column has u_j unique integer values, then this step costs $O(mu_j)$. In the worst case, $u_j = O(n)$, so a single integer-valued column may require $O(mn)$. If $m = n$, this becomes $O(n^2)$. Thus, while sampling is usually cheaper than fitting, high-cardinality integer columns can make the sampling stage substantially more expensive in the worst case.

Table 10: NPGC Hyperparameters

Parameter	Value
Differential privacy parameter (ϵ)	1.0
Neural optimization	None
Marginal modeling	Empirical
Dependency modeling	Gaussian copula relation

Memory complexity. The memory requirements can also be separated into the fitting and sampling stages. During fitting, the algorithm stores the latent Gaussian matrix $Z \in \mathbb{R}^{n \times p}$, which requires $O(np)$ memory. It also stores the correlation matrix, which requires $O(p^2)$, and the learned marginal information. For numeric variables, the fitted model stores the sorted observed values for each column; across all columns, this requires $O(np)$ memory in the worst case. Categorical counts and metadata contribute at most lower-order terms relative to this. Therefore, the overall memory complexity of `fit()` is

$$O(np + p^2).$$

Sampling memory. During sampling, the algorithm stores the independently generated Gaussian samples, the correlated Gaussian samples, and the final synthetic table, each of size $m \times p$. Although these objects may coexist temporarily, their combined memory usage remains $O(mp)$ up to constant factors. The learned correlation matrix again requires $O(p^2)$ memory. Hence, the typical memory complexity of `sample()` is $O(mp + p^2)$.

Integer-valued columns. As with runtime complexity, integer-valued columns can increase memory usage. When minimum and maximum values are enforced, the inverse mapping step forms a temporary pairwise difference matrix between the generated values and all unique observed integer levels. If column j has u_j unique integer values, this temporary array requires $O(mu_j)$ memory. In the worst case, $u_j = O(n)$, so one such column may require $O(mn)$ additional memory. Therefore, the worst-case memory complexity of `sample()` becomes

$$O(mp + p^2 + mn).$$

ABSTRACT

Large Language Models (LLMs) enable new possibilities for qualitative research at scale, including annotation and qualitative coding of educational data. While LLM-based multi-agent systems (MAS) can emulate human coding workflows, their benefits over single LLM agents for coding remain poorly understood. To that end, we conducted an experimental study of how persona and temperature of component agents of a MAS shapes consensus-building and coding accuracy for dialog segments. LLMs were prompted to code these segments deductively using a mature codebook with 8 codes and high inter-rater reliability derived from prior research. Our open-source MAS mirrors deductive human coding through structured agent discussion and consensus arbitration. Using six open-source LLMs (with 3 to 32 billion parameters) and 18 experimental configurations, we analyze over 77,000 coding decisions against a gold-standard dataset of human-annotated transcripts from online math tutoring sessions facilitated by educational software. Temperature significantly impacted whether and when consensus was reached across all six LLMs. MAS with multiple personas (including neutral, assertive, or empathetic) significantly delayed consensus in four out of six LLMs compared to uniform personas. In three of those LLMs, higher temperatures significantly diminished the effects of multiple personas on consensus. However, neither temperature nor persona pairing led to robust improvements in coding accuracy. Single agents matched or outperformed MAS consensus in most conditions. Qualitative analysis of MAS collaboration and coding disagreement may, however, improve codebook design and human-AI coding.

1. INTRODUCTION

Educational research has seen a recent surge of multimodal data produced by increasingly rich forms of user-system interaction [3, 41, 8, 4]. One illustrative example is remote tutoring, where humans and students converse in the process of using educational technology [55, 61]. These contexts produce transcripts and logs of chat interactions that promise rich insights into the learning process. The surge in rich data stands in contrast with the process of analyzing it: qualitative analysis methods for such data, for example, thematic analysis (TA), requires human skills and domain knowledge and scale poorly with the size of the analyzed dataset. Novel methods of drawing insights from this data are needed, and educational data mining can contribute to the analysis and evaluation of these methods.

To that end, the potential of LLMs for qualitative research has sparked interest among the educational research community. Prior work has demonstrated the promise and limitations of using LLMs for inductive and deductive coding, raising questions about reliability, interpretability, and the degree of human oversight needed. Recent developments in LLM-based multi-agent systems (MAS) offer new possibilities for enhancing the robustness of LLM-based coding, mimicking the collaborative nature of human analysis by distributing roles [48, 44, 42]. One key benefit of MAS is that they can implement LLM self-consistency through repeated stochastic generation and aggregation across multiple agents (e.g., re-prompting and majority voting), improving robustness to sampling variance [60]. This study builds on that foundation to comprehensively study how temperature and consensus tuning can improve thematic coding accuracy and consensus in educational research settings, if at all.

The contributions from this research are three-fold. First, we introduce a system-centered contribution by developing and empirically evaluating a multi-agent framework for LLM-based deductive coding. The system supports integration of open-source language models and parameter configurations, enabling comparative analyses of their effects on coding reliability, accuracy, and interpretability. Leveraging this framework, we provide a novel empirical comparison of single-agent and multi-agent coding performance aligned with human-coded data, revealing that consensus-making reliably improves coding accuracy only within our sample for a single LLM and code at low temperatures. Second, we

systematically evaluate how different LLMs, agent persona congruency, and temperature settings influence consensus-building outcomes using mixed-effects modeling across six models of varying size (3 to 32 billion parameters). This addresses a critical gap in the literature; while persona traits and temperature are theorized to capture multiple perspectives [64, 53] and affect the degree to which agents converge on a shared interpretation or consensus [48], their specific impacts on coding dimensions have lacked rigorous evaluation in prior work [29, 50, 44, 42]. Third, we present a qualitative analysis of agent deliberation traces to examine how consensus emerges through design choices that closely parallel human-led thematic analysis practices [47]. By identifying how and when agents revise or reinforce codes during deliberation, this analysis offers deeper insights into the interpretability and epistemic limits of LLM-driven qualitative coding.

To build a methodology for investigating this, we draw from [4], who employed GPT-4 in a hybrid collaboration with human coders to co-construct codebooks for analyzing tutoring transcripts in math learning facilitated by technology. We extend this work to evaluate how varying system configurations, including different LLMs, persona prompts, and temperature values, shape the thematic outcomes and influence multi-agent coding, focusing on consensus-making and accuracy against human ground truth. Our findings advance theoretical understanding and practical implementation of LLM-assisted qualitative methods by identifying how, when, and why MAS may improve qualitative coding accuracy. Our open-source MAS is compatible with any open-source LLM via Ollama [37] and produces deliberation traces between agents that are scrutable for researchers and practitioners. This work contributes to ongoing efforts in the field to optimize LLM-mediated interpretive tasks through deliberate system design and structured variation in agent behavior. The research questions guiding this study are as follows:

- **RQ1:** How do agent persona and temperature influence the frequency of consensus-building in a multi-agent LLM system for thematic coding?
- **RQ2:** Does multi-agent coding with different agent personalities and temperature settings improve upon single-agent coding compared to the human baseline?
- **RQ3:** What qualitative patterns of successful consensus-making arise in multi-agent thematic coding?

2. BACKGROUND

This section reviews relevant literature on thematic analysis, the automation of qualitative coding with LLMs, and the emergence of MAS to enhance reliability and interpretability in LLM-driven analysis. It outlines the core processes of thematic analysis (foundational to qualitative coding and established research methods), discusses recent studies that apply LLMs to automate coding, and highlights how multi-agent approaches aim to simulate human collaboration to improve consensus and accuracy.

2.1 Thematic Analysis

Qualitative methods like TA offer the potential to move beyond quantitative metrics, which often fail to capture the nuanced dimensions that shape learning processes. TA addresses this limitation by uncovering latent themes and patterns through an interpretive and negotiated process among researchers, ultimately leading to the emergence of meaning [10, 11]. TA can be conducted using either an inductive or deductive approach. Inductive analysis follows a bottom-up approach, in which themes emerge from the data rather than being shaped by pre-existing theories or frameworks. In contrast, deductive analysis takes a top-down approach, guided by predefined theoretical constructs [10].

There are different types of thematic analysis, including reflexive thematic analysis, grounded theory, and content analysis. While these approaches are foundational for conducting qualitative research, translating their underlying theoretical frameworks into consistent practice can introduce variability, depending on a range of contextual factors [4, 32]. To mitigate these challenges, researchers often adopt strategies such as: (1) ensuring transparency in the analytic process and thoroughly documenting procedures, (2) iteratively refining the codebook, and (3) establishing inter-coder reliability [4]. Although these practices enhance the trustworthiness of the findings, they are also time-intensive, particularly when working with large datasets. As a result, there is growing interest in leveraging LLMs to streamline and support the TA process. The following section explores this emerging area in greater detail.

2.2 Automated Thematic Analysis

Although semi-automated, qualitative data analysis tools such as *NVivo* [21], *ATLAS.ti* [51], and *MAXQDA* [25] support coding efficiency; they rely on manual coding and interpretation, limiting scalability. Recent work has explored the potential of LLMs to automate or semi-automate TA. For instance, [4] compared four coding workflows—manual, automated, and two hybrid GPT-4-assisted approaches—on Algebra I tutoring transcripts. Hybrid methods yielded codebooks with greater clarity, mutual exclusivity between categories, and inter-coder agreement than either fully manual or fully automated approaches. Similarly, [33] evaluated GPT-4 across three educational datasets, testing various prompting strategies (e.g., zero-shot, few-shot, contextual). GPT-4 achieved substantial agreement with human coders ($\kappa > 0.70$ for 25 of 34 constructs), although it struggled with abstract or ill-defined categories. These findings highlight the potential of LLMs for inductive analysis, though a continued need for human oversight remains.

LLMs have also been studied for deductive coding. [63] found GPT-4 outperformed nCoder in recall and provided helpful feedback for construct refinement, though nCoder achieved higher accuracy. Likewise, [43] proposed GROPROE, an iterative prompting method for deductive TA using theory-based codebooks. After 60 prompt refinements, GPT-4 matched human inter-rater agreement (76%) on student reflections but remained prone to sycophantic bias. As [17] highlights, interpretive nuance and contextual understanding still require human judgment.

While promising, these approaches often depend on human feedback and small datasets. In contrast, recent work using MAS for TA, such as Thematic-LM [42], suggests that distributed LLM agents may support more autonomous and

scalable analysis. The following section introduces this and similar MAS-based approaches to thematic analysis.

2.3 Multi-Agent Thematic Analysis

Most prior work on LLM-assisted qualitative analysis has relied on single-agent models, meaning LLMs are applied to code data and no other LLM prompt processes or interacts with intermediate LLM output [33, 63, 17]. Past work has identified several limitations of this approach. [42] highlights three key issues: (1) the need for human oversight to monitor and contextualize LLM outputs; (2) limited perspective diversity, as single agents often mirror the coder's viewpoint; and (3) the absence of iterative refinement, hindering the model's ability to revise earlier codes.

In response, recent studies have explored multi-agent LLM systems to address these challenges (e.g., [48]). For instance, [42] proposed Thematic-LM, a multi-agent framework assigning distinct roles—such as coder agents, reviewers, and aggregators—to reduce thematic homogenization and enhance representativeness. Extending this approach, [44] demonstrated the effectiveness of MAS across various qualitative methods (e.g., grounded theory, content analysis), reporting an 87% practitioner satisfaction rate and improvements in both efficiency and scalability.

However, none of these studies have systematically explored how system parameters, such as temperature or agent persona, shape the effectiveness of consensus-building or coding accuracy in MAS. Moreover, while previous work has proposed architectural frameworks for role assignment among agents, there has been little empirical analysis of how these configurations influence the interpretability or consistency of LLM-generated codes. This leaves open critical questions about whether MAS approaches yield more reliable or representative qualitative insights than single-agent models and under what conditions such improvements occur, a gap we address through systematic prompt experimentation.

2.4 Consensus in Multi-Agent LLM Systems

Consensus seeking is a fundamental challenge in MAS, where agents with divergent initial states must converge toward shared solutions. In LLM-based MAS, agents naturally adopt an "average strategy" when no explicit consensus instructions are provided, computing the average of all agents' current states [14]. [14] have identified several critical factors that affect consensus dynamics in MAS-LLM systems, including the number of agents, agent persona, and temperature settings. For example, they demonstrated that suggestible agents in two-agent configurations can exhibit oscillatory behavior due to mutual influence without resolution. However, increasing the number of agents stabilizes the system through majority-supported states. In two prior studies, mixed-persona systems with heterogeneous agent groups achieved superior performance in complex reasoning and consensus tasks compared to homogeneous groups [14, 64]. However, we are not aware of any study that has demonstrated similar effects in qualitative coding. Moreover, these findings reveal that consensus achievement in MAS depends on agent characteristics, system parameters, and task requirements rather than purely on algorithmic design.

2.5 LLM Persona Research

Persona and Personality Traits in LLMs. With the advent of LLM agents and their ability to mimic human linguistic behavior, many researchers used the same questionnaires designed to understand human traits (stable differences between people), such as the Big Five personality model, with LLM agents [22]. In this literature, personality is defined as a stable set of dispositions. In contrast, a persona refers to a situationally induced role or style specified through prompting, instructions, or contextual framing (potentially aligned with a certain personality trait). The results of persona research in LLMs have been mixed. Some research has shown that LLM agents can exhibit intrinsic and extrinsic personality traits both lexically and in decision-making or downstream tasks (e.g., [49], [22], and [56]). For example, [22] found that GPT-3.5 and GPT-4 responses matched designated Big Five personality profiles when appropriately prompted. On the other hand, growing evidence points to significant instability in LLM persona expressions. For example, [20] demonstrated that trivial changes to prompt phrasing or answer ordering can dramatically alter LLM personality tests. These findings reveal that although LLM "personalities" color dialogue style and behavioral patterns, the mechanisms underlying these effects remain poorly understood. Chittem et al. [16] further argues that reliably inducing traits in LLMs requires continuous, nuanced control beyond simple instructions. This uncertainty raises critical questions about the extent to which induced personalities impact LLM agent performance and decision-making in real-world applications, such as deductive coding, a gap that our work aims to address.

Multi-Agent Systems and Personality. More directly relevant to multi-agent collaboration, research by [64] and [14] demonstrated that systems composed of agents with distinct personalities, such as "stubborn" and "suggestible" agents, outperform homogeneous agent groups in complex reasoning and consensus tasks. In particular, [14] showed how personality traits interact with network topology to influence convergence dynamics: stubborn agents tended to lead to consensus outcomes, sometimes producing hierarchical structures or clustering effects, especially in partially connected networks. Therefore, embedding diverse, interacting personalities in multi-agent LLM systems could also shape the consistency, agreement, and accuracy of multi-agent TA systems, though broader evidence of such effects, especially for qualitative coding, is lacking in the literature. In contrast, when most or all agents are stubborn, consensus becomes significantly harder to achieve regardless of the number of agents, since such agents rarely revise their positions and the likelihood of deadlock increases [14]. Our study builds on this foundation by contrasting dominant and permissive LLM personas, and their combinations, in a rigorous experimental setup. [64] suggested that odd-numbered agent groups outperformed even-numbered ones by avoiding tie situations during consensus. Therefore, each of our experiments introduces a third agent whenever consensus between the first two agents is not achieved.

3. SYSTEM DESIGN

3.1 Emulating Human Coding

Our system design follows established qualitative research practices for deductive coding with a predefined codebook.

In standard approaches, at least two trained coders independently assign codes to data segments, assess inter-coder reliability, and iteratively refine codes through discussion, with a third coder often serving as an adjudicator in cases of disagreement [4, 63, 9, 13]. We replicate this process by deploying multiple independent AI agents to initially code identical data segments without access to one another's coding decisions, thereby preserving analytical independence. For each coding turn, agents were provided with the current text, the LLM conversation history for the data point being coded (up to the current turn), the instructional prompt, and the codebook. Whereas human coders typically receive explicit training to establish a shared understanding of the coding procedure, AI agents were guided by a system prompt that provided the necessary codebook, contextual information, and procedural instructions. Disagreements were resolved by introducing a third, neutral agent who adjudicated them.

Inter-Coder Reliability (ICR) assessment Agreement between coders is assessed using statistical measures to evaluate consistency [15, 12]. For instance, according to the literature, a Cohen's kappa of 0.61 or higher indicates substantial agreement between the two coders [28]. Until such an agreement is reached, individual inconsistencies are revisited. This step is approximated in our system by determining whether the two agents fully align on their coding to assess consensus among AI agents over individual data segments.

Disagreement resolution. When coding discrepancies arise, human coders typically engage in structured discussions to reach consensus. This process is often facilitated by a third party or formal consensus process, especially if the discussion between agents does not resolve the disagreement. The new party can activate the majority rule by being the odd addition, or might be a more experienced researcher who can overrule the other coders and make the final decision [38]. To replicate this critical step, we implemented a consensus agent with a balanced, reflective personality that, upon detecting repeated disagreement (in the previous two turns) between the two coders, makes final coding decisions by considering the original coding prompt, each agent's initial classification, and each agent's discussion.

3.2 Injecting Personality

Methodological Foundation and Trait Selection. Building on the foundations established in Sections 2.4 and 2.5, we follow recent research that demonstrates that LLMs can be effectively prompted to exhibit distinct persona profiles [36]. Prior work has established that certain dimensions of the Five-Factor Model exert greater influence in group settings than others. [5] found that while conscientiousness showed no relationship to processes and outcomes at individual or group levels, the proportion of extraverted members correlated with enhanced task focus and group performance. Similarly, [35] demonstrated that agreeableness predicted superior interpersonal cooperation and reduced conflict in team environments. Based on these empirical findings, our study focuses on agents with either high extraversion or high agreeableness, alongside one agent maintaining neutral levels across all traits. This design allows systematic examination of how assertiveness versus cooperation influences consensus formation in multi-agent qualitative coding tasks [58]. The selection of these specific traits is further justified by research showing that prompt politeness and assertiveness significantly influence LLM compliance, including in the generation of false information [59]. In consensus-making scenarios during qualitative coding, dominance or compliance behaviors may yield different outcomes depending on the accuracy of the initial codes. To investigate these dynamics, each personality trait was implemented through prompt engineering and evaluated for its impact on consensus formation, alignment with human codes, and fallback frequency. Here are the personality profiles used in this study:

Bold and Dominant but Elaborative: This personality profile, used for coder agents, reflects assertiveness and extraversion while maintaining a willingness to engage in dialogue. It corresponds to the "bold" category in personality type and was used in multi-agent scenarios. **Empathetic and Open-Minded:** A permissive and collaborative profile emphasizing agreeableness and openness. Labeled as "empathetic" in personality type, this profile was also used in multi-agent settings to encourage broad discussion and interpretation. **Balanced and Reflective:** A neutral profile was applied to the single-agent (control condition) and consensus-agent.

3.3 Large Language Models

Another challenge in prompting LLM agents to behave in a certain way is that some LLMs tend to have an inherent personality as reported by [39] and [26]. These inherent traits can lead to variability in how models respond to induced personality prompts; some may resist the induced traits and revert to their default behavior, while others may behave inconsistently or unpredictably. [49] and [39] demonstrated that **instruction fine-tuned models** exhibit more reliable and consistent personality traits compared to their base (non-fine-tuned) counterparts. Given our focus on understanding the effect of personality injection and practical resource constraints, we prioritized LLM prompt instruction over task- or persona-specific fine-tuning. To investigate how personality and behavioral consistency vary across different architectures, we evaluated a diverse set of open-source language models spanning parameter sizes and development lineages. The models included in our analysis are:

LLaMA 3.2 3B [57], developed by Meta, is a lightweight decoder-only transformer model designed for efficient inference in resource-constrained settings, while still performing well on reasoning and multilingual tasks. This model is not instruction-fine-tuned by default. **OpenHermes V2 (7B)** [54] is a community-developed model based on the Mistral architecture, fine-tuned for instruction-following. It demonstrates strong performance on multi-turn dialogue and reasoning benchmarks such as MT-Bench and ARC, ranking among the top-performing 7B open models in humanaligned chat tasks [65]. **WizardLM 2 (7B)** [62] is jointly developed by Microsoft and Alibaba, optimized for complex multi-turn instruction tuning and is particularly effective in multi-step reasoning and contextual dialogue. **Phi 3 (14B)** [2] is released by Microsoft, utilizes a dense transformer architecture, and is instruction fine-tuned. This model is trained on a compact, highly curated dataset of synthetic educational material; it performs competitively on benchmarks involving reasoning, math, and safety. **Mistral-small 3.2 (24B)** [34] is an upgrade of their Small-3.1 24B model, op-

timized for instruction-following, reducing repetition, and improving function calling. This high-capacity model uses grouped-query attention for efficient inference, excelling at multilingual and factual question-answering tasks. **Deepseek R1 (32B)** [19] is a large decoder-only model developed by DeepSeek AI, trained on both code and natural language using a mixture-of-data approach. It achieves strong performance across a variety of benchmarks, particularly excelling in reasoning-heavy tasks and long-context understanding.

Our system and experimental evaluation code are fully open-source (repo: [1]) and compatible with the Ollama open-source framework for LLMs [37]. Codebooks and data can be requested from [4] to reproduce our analysis results using our code. The same applies to the LLM collaboration data, which often contains verbatim copies of the input data and is therefore under the same data-sharing constraints.

4. METHODS

4.1 Study Context

4.1.1 Data Set

The data for this study were originally collected and annotated by [4] and shared with the research team of the present study. The mentioned study was conducted using transcripts from high-dosage math tutoring sessions across two schools, in which trained tutors provided personalized, small-group instruction to support students' mathematics learning. The transcripts were drawn from four 60-minute virtual tutoring sessions. The participants were 9th-grade students enrolled in Algebra I, attending high-poverty schools in an urban region of the northeastern United States. The sessions took place between 2022 and 2023. For this study, we analyzed 579 tutor-student dialog segments from three session transcripts. Each segment is treated as an individual data point for model evaluation.

4.1.2 Codebook Development

Our annotation scheme builds on the hybrid human-AI codebook developed in [4], which was rated more favorably by human reviewers than exclusively LLM-built codebooks and found to support more reliable hybrid coding. The codebook includes eight high-level categories (see also study repository [1]): **Greetings, Instructions, Guiding Feedback, Aligning to Prior Knowledge, Understanding/Engagement Tutor, Technical or Logistics, Encouragement** and **Time Management**.

4.2 Multi-Agent System

We developed a multi-agent system to simulate and evaluate AI-assisted qualitative deductive coding based on a codebook. The system includes four components: (1) a single-agent coder, (2) a dual-agent discussion module, (3) a consensus agent, and (4) a hybrid human-AI dataset for benchmarking. All agents operate on the same codebook (see Section 4.1.2), implemented as a labeled dictionary of binary flags for each codebook category. (e.g., "Tutor: What's good, XX? {'Greeting': 1, 'Instruction': 0, ...}"). Each utterance includes a human-generated reference code derived from double-coding and resolution by trained annotators. The codebook is available in the digital appendix [1]).

The *SingleAgentCoding* module simulates individual annotation. It instantiates a single language model with a fixed persona (e.g., neutral, empathetic, or bold; see Section 3.2) and instructs it to assign codes to a given utterance based on the codebook definitions. The dialog segment and the full codebook are included in the user prompt. To simulate inter-annotator discussion, the *DualAgentDiscussion* module employs two distinct agents with personalities. Agents take turns critiquing each other's code using textual reasoning and are prompted to reflect on discrepancies across multiple rounds. In a post-processing routine, the discussion is checked for completeness, and annotations are extracted. The *ConsensusAgent* module finalizes coding by reviewing both agent responses. It is designed to explicitly identify disagreement and generate a resolved label. The consensus agent maintains a balanced, reflective, neutral persona (similar to the single-coding agent in the control condition), emphasizing justification and adherence to the codebook. The agent receives the data segment utterance and both prior agent responses for reference. The full MAS setup and prompts are available in the digital appendix [1].

4.3 Experimental Conditions

We conducted a 3×2 factorial experiment varying *decoding temperature* (0.0, 0.5, 1.0; ranging from low to high) and *persona pairing* (congruent vs. incongruent). Persona pairing was defined based on whether the two simulated agent personalities (*persona_a* and *persona_b*) matched (congruent) or differed (incongruent). The six pairings included three congruent pairs (balanced-balanced, bold-bold, empathetic-empathetic) and three incongruent pairs (bold-empathetic, balancedbold, balancedempathetic). The rationale for this design was to investigate whether multiperspectivity, operationalized as persona diversity, influences coding accuracy and consensus formation in LLMs. Each of the 18 configurations was run on a shared dataset of 579 utterances. Agents were instantiated with systematically varied personality traits drawn from three archetypes: *neutral*, *dominant*, and *permissive*. We chose these three traits as the politeness or assertiveness of prompts has been shown to influence LLM compliance [59] (see Section 3.2 for more detail).

Implementation Details. The system uses the Ollama API [37] to interface with local large language models (e.g., WizardLM 2 7B). Personalities and roles are injected via structured system prompts that emphasize justification and brevity to keep context windows manageable. Experiments are orchestrated in Python. A single experiment took about 2 hours on a standard MacBook Pro with an M1 CPU (except for DeepSeek R1, which was run on larger machinery). Running the MAS with the DeepSeek R1 model for a single data point on an NVIDIA A100 GPU took, on average, about 60 seconds. We computed the % **Agreement Rate** for each experiment, label, and condition, which measures the proportion of utterances in which the final system-assigned code matched the human-coded ground-truth label. The system stores outputs from all modules, including raw and expanded codes, intermediate discussion content, and final consensus decisions. The output is a structured CSV file used for analysis and comparison with human-coded data.

4.4 Data Analysis Methods for RQ1 and RQ2

To address RQ1, which examines the impact of persona and temperature on consensus-making, we analyzed how agent

persona pairings and decoding temperature influence the type of consensus achieved during dual-agent discussions. We categorized consensus outcomes into three types: (1) first consensus, where both agents agreed from the start; (2) resolved consensus, where initial disagreement was successfully resolved during discussion; and (3) no consensus, where agents failed to converge on a shared label and the consensus agent needed to enforce consensus. Our focus here lies in examining the likelihood of first consensus and no consensus across persona and temperature conditions.

We estimated generalized linear hierarchical mixed-effects modeling with a binomial link function using the lme4 package in R [6], predicting each outcome type as a function of agent persona congruency (i.e., matched or mismatched) and temperature (0.0, 0.5, or 1.0; see implementation details in Section 4.2), while controlling for random intercepts by text unit. This adjustment for the text unit is necessary because the same data segments are coded multiple times in our experiments and could systematically vary in difficulty, making it harder to reach consensus (e.g., because some texts are more ambiguous than others). We estimated three generalized linear mixed-effects models with a binomial link function to predict the likelihood of three consensus outcomes: initial, delayed, and no consensus, all following the same formula structure (but with different outcomes):

$$\begin{aligned}\text{logit}\left(\Pr(\text{Consensus}_i = 1)\right) = \\ \beta_0 + \beta_1 \cdot \text{Congruency}_i + \beta_2 \cdot \text{Temperature}_i + \\ \beta_3 \cdot (\text{Congruency}_i \times \text{Temperature}_i) + u_{\text{text}[i]}\end{aligned} \quad (1)$$

In both models, Congruency_i indicates whether the two agents in condition i had matched personality traits, and Temperature_i refers to the decoding randomness used by the model during generation. The interaction term captures how the effect of congruency varies across temperatures. The term $u_{\text{text}[i]}$ is a random intercept for each text unit, accounting for potential variation in the difficulty or ambiguity of individual utterances. We highlight that we separately repeated this procedure for each language model.

To evaluate whether MAS coding leads to greater alignment with human annotations than single-agent outputs (RQ2), we analyzed 77,273 individual coding decisions (treating assignment of each codebook category as a distinct binary decision). Each decision represented a binary classification across a fixed codebook, annotated by a human coder, a single-agent model, and a final consensus model. For each decision, we computed whether the model's label matched the human label, both for the baseline single-agent in the control condition and for the MAS's final output. We, again, organized experimental conditions along two dimensions: decoding *temperature* (0.0, 0.5, or 1.0) and *agent persona pairing congruency* (incongruent vs. congruent; see Section 3.2 for full details on persona pairing). We fit six models separately by LLM and fit a generalized linear mixed-effects model predicting whether the final consensus matched the human label, using temperature, persona group, and their interaction as fixed effects, and including random intercepts for each utterance and code category (since binary coding decisions are treated as separate observations in this model, as opposed to RQ1):

$$\begin{aligned}\text{logit}\left(\Pr(\text{FinalAgreement}_i = 1)\right) = \\ \beta_0 + \beta_1 \cdot \text{Temperature}_i + \beta_2 \cdot \text{Congruency}_i + \\ \beta_3 \cdot (\text{Temperature}_i \times \text{Congruency}_i) + \\ u_{\text{utterance}[i]} + u_{\text{code}[i]}\end{aligned} \quad (2)$$

As we did not find any significant and robust trends in how our experimentally manipulated dimensions impacted coding accuracy, we conducted an exploratory analysis. For this analysis, we recoded the persona factor into three levels (includes assertive agent, includes empathic agent, or both), ignoring the neutral-neutral pairing. We then tested model experiments individually (6 LLMs x 8 codes x 3 persona pairings x 3 temperatures = 432 contrasts). To evaluate whether final consensus codes are more closely aligned with human annotations than those produced by a single agent, we performed a paired samples t-test. This test aims to compare the percentage of correct code between the single agent and MAS across all contrasts. The Benjamini–Hochberg (BH) method was used to control the false discovery rate [7], given the large number of comparisons. We aimed to determine whether any condition, combination of LLMs, code, or experimental parameter would show reliable MAS improvements relative to the single-coder baseline, and whether any patterns emerged across conditions that produced MAS advantages in qualitative coding accuracy.

4.5 Qualitative Analysis Methods for RQ3

Our system design features the negotiation of codes through conversational turns, similar to how codes would evolve in a human conversation. Beyond this similarity, our system records all conversational turns, which could be considered recordings of code negotiation in the human analogy. Hence, the system offers a level of transparency not typically found in human coder teams, enabling analysis of the rationale behind each piece of code. We took advantage of this level of transparency to analyze *why* MAS configurations could achieve or fail to achieve the quality of human coding.

To understand the mechanisms behind coding shifts that can speak to patterns of successful MAS collaboration in our context (RQ3), we conducted an ad-hoc qualitative analysis of the *Guiding Feedback* category for OpenHermes, which showed statistically reliable improvements from single- to multi-agent coding, aligning more closely with human consensus. Among 9,735 total coded turns where no initial consensus was reached between the two agents, 71 cases involved *Guiding Feedback* being correctly removed during consensus (according to human ground-truth codes), and 79 cases involved it being correctly added. Two independent human coders analyzed these instances in a spreadsheet. The question guiding the coders' analysis was whether any notable patterns of the agents' consensus-making could explain the observed performance improvement. Coders analyzed: (a) how agents justified their coding decisions, (b) the internal consistency between rationale and codes of agents, (c) the external consistency between turns of agents, and (d) whether certain personalities tend to dominate or concede during discussions. Afterwards, they held a meeting to discuss their findings. In cases of disagreement, they reached consensus through discussion and organized such instances under shared themes, such as Hallucination.

5. RESULTS

Figure 1 shows the distribution of consensus outcomes across LLMs. Consensus frequencies substantially varied. DeepSeek-R1:32B reached no coding consensus in fewer than 0.1% of cases, whereas Llama:3b did not reach consensus in 21.7% of cases. Notably, for all LLMs, immediate consensus in the first round was the most common outcome.

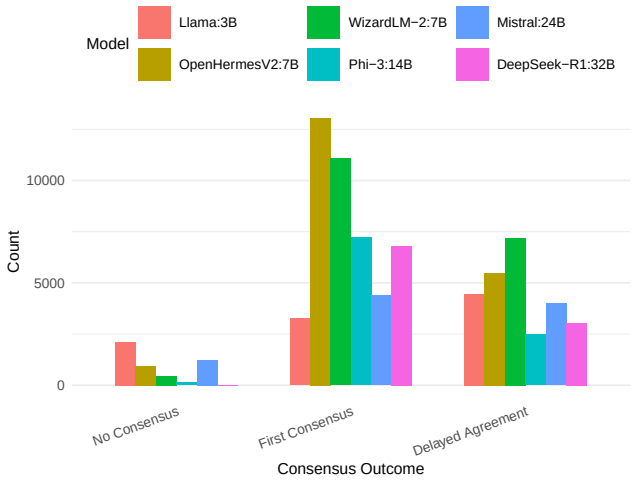

Figure 1: Distribution of consensus outcomes over total number of dialog segments and experiments (No Consensus, First Consensus, Delayed Agreement) across the six LLMs.

The distribution of codes, expressed as percent base rates from human coding, included: Aligning to prior knowledge (6.44%), Encouragement (5.58%), Greeting (5.15%), Guiding feedback (6.44%), Instruction (9.01%), Technical or Logistics (0.43%), Time Management (1.29%), and Understanding / Engagement–Tutor (26.2%).

To investigate how agent persona congruency and temperature influenced consensus-building, we fit a series of generalized linear mixed-effects models with random intercepts for each text. Models predicted three outcomes: (a) first round agreement, (b) no consensus at all, and (c) delayed consensus (agreement only after a second round). Tables in the digital appendix [1] report odds ratios (OR) and 95% confidence intervals (CI) for each predictor across the three language models. We summarize key findings below.

5.1 RQ1a: Consensus Making Effects

Immediate Consensus. Across all models, higher temperature significantly reduced the likelihood of reaching consensus in the first round ($p's < .001$), with odds ratios ranging from $OR = 0.07$ (OpenHermes-V2:7B) to $OR = 0.59$ (DeepSeek-R1:32B). Incongruent personas significantly reduced consensus likelihood in Llama:3B ($OR = 0.54$, $p < .001$), WizardLM-2:7B ($OR = 0.80$, $p = .010$), Phi-3:14B ($OR = 0.67$, $p < .001$), and Mistral-24B ($OR = 0.79$, $p = .002$), but not in OpenHermes-V2:7B or DeepSeek-R1:32B. Notably, Llama:3B ($OR = 1.96$, $p < .001$) and Phi-3:14B ($OR = 1.76$, $p < .001$) showed significant positive interactions between temperature and incongruency. *Full model results are reported in the digital appendix [1].*

No Consensus. Failure to reach consensus was consistently more likely under high temperature across all LLMs ($p's < .01$), with significantly increased odds in Llama:3B ($OR = 2.06$, $p < .001$), WizardLM-2:7B ($OR = 2.23$, $p = .003$), OpenHermes-V2:7B ($OR = 4.15$, $p < .001$), Phi-3:14B ($OR = 2.58$, $p = .003$), and Mistral-24B ($OR = 3.93$, $p < .001$). In contrast, congruency and its interaction with temperature did not significantly predict no-consensus outcomes in any model (p's $> .450$). DeepSeek-R1:32B was excluded from this analysis due to an insufficient number of non-consensus cases (less than 0.1%). *Full model results are reported in Appendix A in the digital appendix (see digital appendix [1]).*

Delayed Agreement. Higher temperature significantly increased the odds of delayed consensus across all models ($p's < .001$), with odds ratios ranging from $OR = 1.57$ (WizardLM-2:7B) to $OR = 10.28$ (OpenHermes-V2:7B). Incongruent personas were significantly associated with increased delayed agreement in Llama:3B ($OR = 1.69$, $p < .001$), WizardLM-2:7B ($OR = 1.24$, $p = .011$), Phi-3:14B ($OR = 1.52$, $p < .001$), and Mistral-24B ($OR = 1.21$, $p = .008$), but not in OpenHermes-V2:7B or DeepSeek-R1:32B (p's $> .328$). Significant negative interactions between congruency and temperature emerged in Llama:3B ($OR = 0.52$, $p < .001$), Phi-3:14B ($OR = 0.58$, $p < .001$), and Mistral-24B ($OR = 0.80$, $p = .040$), suggesting that when generation is more stochastic, the disruptive effects of persona mismatch on delayed agreement are attenuated in some LLMs. *Full model results are reported in the digital appendix [1]).*

Taken together, these findings show that **temperature robustly delays consensus across all LLMs**, while **persona congruency exerts more selective effects**. Interaction effects were similarly model-specific, but **generally showed that higher temperatures attenuate the effects of persona on consensus.** *See digital appendix for detailed model coefficients [1].*

5.2 RQ2: Human Alignment

Similarly to RQ1, we modeled the likelihood of final alignment with human judgments as a function of temperature, persona diversity (congruent vs. incongruent), and their interaction, using mixed-effects logistic regression with random intercepts for item and code (e.g., greeting vs. praise). Across all six models, persona congruency and its interaction with temperature showed no significant effects on final alignment ($p's > .149$). Temperature showed a small but significant negative association with alignment in OpenHermes-V2:7B ($OR = 0.88$, $p = .003$) and Mistral:24B ($OR = 0.85$, $p < .001$), but not in other models ($p's > .158$). Overall, final alignment with human judgments remained largely unaffected by the persona pairing or temperature manipulation, and no single parameter produced reliable improvements in coding accuracy. *See Appendix B for detailed model coefficients in the digital appendix [1].*

To further explain these findings, Table 1 summarizes the overall percentage of agreement (i.e., alignment with human coders) for each model under both single-agent and multi-agent (final consensus) coding conditions, including 95% confidence intervals.

Table 1: Percentage agreement (aligned responses) by model with 95% binomial confidence intervals.

Model	Final Consensus (%)	Single Agent (%)
DeepSeek-R1:32b	90.0 [89.8, 90.3]	89.9 [89.6, 90.1]
Llama:3B	81.6 [81.3, 81.8]	85.5 [85.2, 85.7]
Mistral:24B	89.3 [89.1, 89.6]	89.7 [89.4, 89.9]
OpenHermes-V2:7B	84.9 [84.7, 85.2]	85.8 [85.5, 86.0]
Phi-3 14B	89.5 [89.3, 89.8]	89.6 [89.4, 89.8]
WizardLM 2:7B	85.6 [85.4, 85.9]	87.2 [87.0, 87.5]

Surprisingly, following Table 1, across all six models, multi-agent coding (i.e., extended deliberation among agents) did not yield substantially better alignment than single-agent coding. In all but one model (DeepSeek-R1:32B), it reduced accuracy, averaged across all experiments. To further examine code-specific effects, we compared alignment between the two coding conditions across different code categories. As shown in Figure 2, some models outperformed others on particular codes, but the pattern of improvement across codes was not consistent across models. Further, the magnitude of performance changes (MAS vs. single agent) also differs across models (notice the difference in y-axis scaling in Figure 2 to improve plot readability). For instance, OpenHermes-V2:7B showed improvements of up to 3% but also performance reductions of about 7% for the MAS on another code. In contrast, DeepSeek-R1:32B did not show average performance changes greater than 0.5%. Beyond OpenHermesV2:7B, no model showed an average performance increase of more than 1%.

The heterogeneity observed in alignment differences raised two questions. First, do comparative differences between multi-agent and single-agent coding vary systematically by item category, temperature, or assigned persona? Second, are the observed differences statistically reliable, or are they false positives due to the large number of comparisons? To address this as part of an exploratory analysis, we applied a modular paired-sample comparison procedure using the Benjamini–Hochberg (BH) method to control the false discovery rate [7]. Specifically, we ran paired t-tests on agreement scores across coding conditions (multi-agent vs. single-agent), grouped by model, persona, temperature, and code category. We adjusted raw p-values using the BH correction across all 432 comparisons (see Section 4.4 for more details).

There were 70 statistically significant contrasts after FDR correction. Of these, a minority (5) showed higher agreement in the multi-agent condition, while 65 showed higher agreement in the single-agent condition. All five positive and reliable improvements were on the code "Guiding Feedback" with the OpenHermesV2:7B model. In other words, we have no evidence that any other positive gains in Figure 2 were due to systematic improvements as opposed to random chance. All of those five included temperatures of 0.5 or lower, and four of those five included bold personalities. Therefore, we conclude that MAS improvements in our dataset were only reliable for a specific model and code. We have no further evidence that consensus-making improves the accuracy of qualitative deductive coding with LLMs.

5.3 RQ3: Qualitative Insights

As detailed in the previous section, the OpenHermesV2-7B model showed significantly better alignment with human coders in its multi-agent configuration for the "Guiding Feedback" code. Aligned with RQ3 ("What qualitative patterns of successful consensus making arise in multi-agent thematic coding?"), We ran an investigation into the process of 150 coding conversations for the MAS on temperature and persona settings, showing statistically reliable MAS improvements (see Section 5.2). These coding conversations were characterized by either removing the "Guiding Feedback" during the conversation, aligning with human coding, or adding the "Guiding Feedback" during the conversation, again aligning with the human coding at the end of the MAS conversation. Given that all turns were recorded, we could investigate these successful turns in an exploratory analysis. Two coders each coded 75 conversations in an open coding process, for a total of 900 conversational turns. Notably, we observed that the LLM provided a rationale in only about 80 of 900 conversational turns. In other cases, the LLM explicitly stated that it had no explanation, referenced only a specific data point, or provided no explanation at all. For guiding feedback, the LLM rationale was rare, too, accounting for only 5 of the 80 rationales provided by the agents. Nevertheless, we were able to make several notable qualitative observations about model behavior for this specific subset of the data.

5.3.1 Consistency

Beyond the LLM's difficulty in providing a rationale in every turn as instructed, we also observed issues within the reported codes. For instance, agents sometimes incorrectly reported previous coding when introducing it with the phrase "the previous turn said," even though the previous turn's codes did not align with those statements. Other notable conversational turns involved the complete output of the provided codebook without further explication. Rare hallucinations concerned data points. In these cases, two agents discussed non-existent data points.

5.3.2 New Codes

In four conversations, the agents proposed new categories. In one example, an agent introduced the new code "Understanding / Engagement-Tutor" to their output, explicitly stating "The tutor is providing instruction [in this datapoint] on the next step in the math problem while also addressing potential confusion around variables or notation. However, I would like to add subcode under "Understanding/Engagement-Tutor" as the tutor is checking for understanding by asking, 'What should we do next?"'.

5.3.3 Hallucinated Datapoints

By design, the system analyzes only one data point from the transcript at a time. This means that agents did not have visibility into other codes. Agents sometimes would nevertheless invent and then discuss such data beyond the provided data point. In one instance, in a discussion about the data point "We found them," the second agent mentions in its reasoning that "the tutor asks if the student remembers what a factor is", which is not what the data point contains.

6. DISCUSSION

This study examined the behavior and performance of a multi-agent LLM system for deductive thematic analysis in

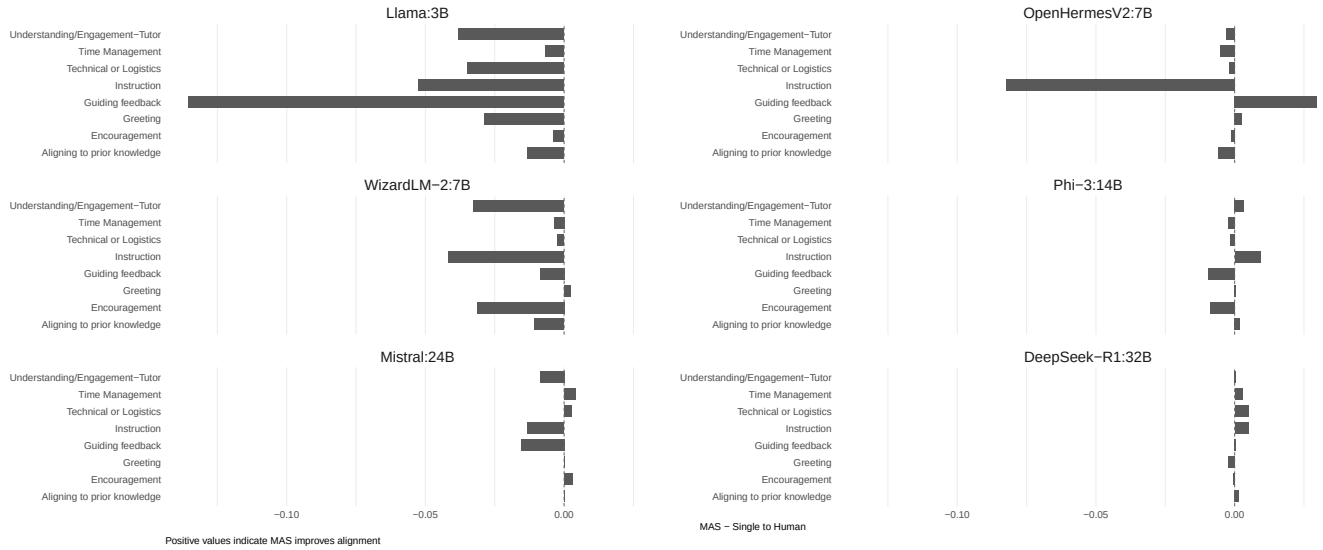

Figure 2: Mean difference in alignment between the MAS and single LLM coding with the human labels. Positive values indicate better MAS performance than single LLM coding.

an educational setting. Building on prior work on multi-agent qualitative coding, we introduced persona-infused agents. We systematically varied temperature to assess their effects on consensus formation and alignment with human-coded data. The resulting open-source system closely aligns with established qualitative coding practices [63, 4, 9].

Although existing studies highlight the potential of multi-agent architectures to emulate human collaboration [42, 64, 44], to our knowledge, no prior work has experimentally evaluated the roles of agent personality, stochasticity, and code-level variation on real-world educational datasets. Beyond empirical evaluation, we considered the implications of these factors for the viability of LLM-based thematic analysis and human–AI collaboration, informed by a qualitative inspection of agent deliberation traces (i.e., justifications for assigning a specific code) to identify conditions under which multi-agent interaction succeeds or breaks down.

6.1 RQ1: Consensus Building

RQ1 results showed that decoding temperature had a consistent, statistically significant effect across all models: higher temperatures reduced the likelihood of immediate consensus and increased the likelihood of delayed agreement and no-consensus outcomes. This aligns with prior findings in LLM generation behavior showing that temperature amplifies response diversity and unpredictability [14, 36].

We predicted that multiple personalities would lead to a more comprehensive consideration of data during coding. The influence of persona congruency, however, was model-specific. While mismatched (i.e., incongruent) personalities reduced immediate consensus across half of the LLMs we investigated, and delayed consensus in four out of six LLMs. These findings suggest that persona-driven heterogeneity may interact differently with LLM architectures. This finding echoes recent studies arguing that the inclusion of personas to induce multiperspectivity in LLMs is a path full of obstacles [29]. In particular, findings highlight that the specific relationships between personas and model behavior remain elusive: they may work in some contexts but not others. Therefore, while they might help in surfacing more diverse model behavior in some cases, we have no evidence that they can be systematically and consistently exploited across settings.

6.2 RQ2: Human Alignment

RQ2 assessed whether multi-agent deliberation improves alignment with human-coded ground truth. Overall, multi-agent systems did not consistently outperform single-agent models. Of 432 condition-level comparisons, only five showed statistically significant improvements. In most cases, consensus coding matched or underperformed single-agent performance. These findings align with prior work [30], which similarly reported higher agreement for a single-agent few-shot approach (82.8%), compared to a multi-agent setup (79.5%). A practical significance of this finding is that the MAS requires substantially more computational resources (see Section 4.3), thereby being substantially less resource-efficient for qualitative coding in our context.

This suggests that extended deliberation among same-model agents does not necessarily yield better accuracy, particularly when the codebook is already well-constructed and disambiguated, as was the case here using a codebook from [4]. This finding challenges the assumption that multi-agent deliberation inherently yields greater interpretive robustness and depth, especially when the underlying language model remains constant and deliberative rounds amount to interacting with variants of the same probabilistic system. Despite strong convergent evidence across several experiments and LLMs showing little tangible accuracy improvement, it is possible that better gains for MAS collaboration could be seen in cases where codebooks are less well-developed or when multiple LLMs collaborate. For instance, a resource-efficient approach could be to use smaller models for initial coding, and larger models only when no consensus is reached.

Such setups, however, are beyond the scope of the present study. Moreover, it may be that the task and the breadth of coding (i.e., assigning multiple codes per turn) are simply too complex for the LLMs studied here [27].

6.3 RQ3: Code-Level Variability and Limits

RQ3 sought to understand where and why MAS may provide additional value in thematic analysis, and what patterns of successful consensus-making emerged. Our observations reveal that, despite the potential of automated systems to assist with qualitative coding, human oversight remains essential for several reasons. First, it could correct technical and formatting inconsistencies, such as invalid code values or schema violations, that undermine data integrity (and can sometimes only be partially mitigated through automated means). In our study, we observed that the only model that reliably improved its own coding in a MAS setup, provided a rationale for coding a data segment in a way that was inconsistent with the instruction in less than 10% of cases. Second, human coders are needed to identify and rectify logical contradictions, hallucinated justifications, or unsupported code assignments [45], all of which compromise the quality of automated annotations. This also echoes findings by [27], who demonstrate that LLM performance often degrades in multi-turn conversations, showing increased unreliability and an inability to reproduce earlier instructions compared to fully specified single-turn instructions. While we re-prompted agents up to once when their formatting was incorrect to mitigate this issue, it is possible that performance losses would be smaller if reprompting were performed more often. However, such reprompting also increases computation time and cost.

Further, our analysis revealed a limited boundary condition under which multi-agent consensus provided its clearest benefit: cases of code ambiguity. Specifically, in the "Guiding Feedback" category, consensus agents helped refine overly broad applications of the code and, in some instances, introduced justified reassignments based on context-sensitive deliberation. However, even in these favorable instances, our qualitative inspection revealed significant transparency issues: agent dialogues lacked consistent internal logic, veered erratically, and often failed to provide reasoning that a human could follow or trust. For example, some decisions appeared arbitrary, with agents deferring to previous turns without clear justification or revising positions without explanation. Similar to how recent research has argued that LLM "reasoning" is merely an artifact of intermediate token prediction [23], so could agentic collaboration for coding be more akin to improving self-consistency via joint prediction [31] rather than a collaborative sensemaking process.

Notably, we observed that coding agents in our experiments sometimes independently proposed new codes, highlighting that consensus mechanisms could benefit human-AI hybrid coding teams [18] in different ways. Rather than maximizing coding accuracy, these systems may be better suited to enhance coding accuracy, codebook development, and challenging existing codes where human coding teams may benefit from new interpretations of data. Our findings thus echo broader calls in the field to retain human expertise in the applications of LLMs for applying expert-level judgment and grading [46, 18].

6.4 Implications for Human-AI Coding

While our system reproduces procedural elements of human workflows (multiple coders, deliberative dialogue, consensus arbitration), it may not reproduce the epistemic stance, contextual grounding, or reflexivity that characterize interpretive qualitative work [11]. Indeed, our qualitative analysis for RQ3 indicated that agents would often overwrite or change their codes without offering explanations (including, at times, in a contradictory manner), even though they were instructed to provide reasoning to the other agent. This behavior highlights that deductive coding with a codebook is a meaning-making process grounded in the researcher's perspective and iterative engagement with data. Our results suggest that MAS cannot reproduce these epistemic dimensions; nor are they designed to. Despite being framed as reasoning systems, they function as complex retrieval and prediction models that infer the most likely next token as argued by [23].

Findings in this study suggest that the value of LLMs in TA may lie less in reproducing consensus than in disrupting it by introducing "alternative perspectives." Prior work shows that combining human and synthetic data can enrich training outcomes, such as in open-response assessment [8]. Our findings similarly support calls for hybrid systems that pair human insight with machine generativity, enhancing qualitative inquiry rather than fully automating interpretive labor [24, 4]. Beyond the manual inspection of agents' consensus processes by humans, data mining methods could also help curate relevant moments in which LLMs question or struggle to disambiguate individual data segments or codes, helping surface analytically ambiguous cases for focused human review [52]. Furthermore, detailed analysis of agents' deliberation traces might give better insights into the coding process [30]. In addition, research has shown that LLM outputs can vary significantly depending on how prompts are phrased (e.g., [20]), opening yet another perspective for future work.

6.5 Limitations and Future Work

Several limitations contextualize these conclusions. First, we relied on a single dataset and a highly refined codebook, previously validated through hybrid human–AI processes [4]. The strong performance of the single-agent condition may reflect the maturity and clarity of this codebook as well as characteristics of the coding task. Future work could analyze the impact of codebook size, along with parameters such as the type of training dataset and domain. Second, the system uses multiple instances of the same base model, prompted differently. While personalities were carefully engineered and experimentally compared (as well as theoretically justified; see Section 3.2), the agents were instantiated solely through prompt-level instructions and all rely on the same underlying architecture. Although some research has demonstrated that LLMs tend to prefer the output generated by their own [40], it remains an open question whether multi-agent diversity derived from different model families (e.g., mixing Claude, GPT-4, LLaMA), as well as more extended and direct interactions between agents, would lead to even richer or more robust consensus processes. Third, while we focused on deductive coding tasks, future studies might examine inductive coding or mixed-methods settings where codebook refinement and creation are explicitly part of the analytic process [4].Finally, given that DeepSeek-R1, the most reasoning-intensive model

in our study, did not yield accuracy gains over single-agent coding, future work could examine whether the deliberation traces produced by such models offer utility beyond accuracy, particularly for codebook refinement [52].

7. CONCLUSION

As educational technologies generate increasingly rich textual data, such as chat and audio transcripts, methods for annotation require careful validation. Large language models have drawn attention for their potential to automate qualitative coding at scale. This study examines how multi-agent configurations of LLMs affect deductive coding processes and outcomes. Although multi-agent systems are often assumed to improve reliability and interpretive depth, our results challenge this assumption. Across experiments with six open-source LLMs, multiple persona pairings, and temperature settings, we find that multi-agent structures strongly shape consensus dynamics, influencing when agents converge or diverge, with persona effects varying across models. However, these changes yielded minimal and highly conditional accuracy gains.

Multi-agent deliberation only marginally outperforms single-agent predictions, and only under narrow conditions involving a specific model, code category, low temperature, and an assertive agent. This calls into question the reliability of agent collaboration as a general-purpose method for improving accuracy or diversity in deductive qualitative coding. Instead, our qualitative analyses suggest that MAS are better suited to exposing ambiguity, prompting codebook revision, and surfacing interpretations that human-only teams might miss. By showing when multi-agent systems do not improve coding, this work helps constrain overgeneralized claims about agentic LLM collaboration.

The Cognitive Cost of Poor Item Design: How Item-Writing Flaws Shape Response Time and Difficulty Across Assessment Domains

ABSTRACT

Item-writing flaws (IWFs), violations of established guidelines for constructing multiple-choice questions, are known to compromise assessment quality. Their effects on item difficulty have proved inconsistent, with flawed items sometimes appearing easier, sometimes harder, and often no different from well-constructed items. We propose that this reflects a measurement problem, as different IWFs impose distinct cognitive demands that cancel or dilute when aggregated. Drawing on cognitive load theory, we classify 19 automatically detected IWFs into three categories of cue-giving, confusion-inducing, and structural complexity based on their expected cognitive function. Analyzing 1,230 items across three domains (medical licensure, K-12 mathematics, and university computer science), we find that each domain exhibits a different mix of IWFs rather than simply more or fewer flaws. Flaws categorized as confusion-inducing consistently increase response time by 14-29% across all three datasets, while cue-giving and structural flaws show no significant effects. This pattern holds across all three datasets, with no significant flaw-by-dataset interactions, suggesting the effect is robust to the differences in subject matter. Bootstrap mediation analyses reveal that confusion-inducing flaws increase processing time, which in turn associates with greater difficulty. This indirect effect is 2.5 times the magnitude of the aggregate indirect effect. These findings suggest that item quality improvement efforts should prioritize confusion-inducing flaws, which are the primary source of unnecessary cognitive burden on examinees.

Keywords

Assessment Quality, Response Time, Question Difficulty

1. INTRODUCTION

Multiple-choice questions (MCQs) remain the most widely used assessment format in education, certification, and professional licensure, where their quality directly affects what we can validly infer about the knowledge and skills of students [58]. With generative AI now accelerating item writing, quality is both more necessary and more possible [4]. Clear standards govern how to create high quality questions, but violations of those standards, item-writing flaws (IWFs), continue to appear even in commercial e-learning instruction [9, 36]. This compromises construct validity, fairness, and the interpretability of learning analytics derived from these assessments [12, 56]. IWFs impose unnecessary cognitive load as students interpret unclear wording rather than demonstrate knowledge, artificially inflating time-on-task through extraneous processing [44, 26, 53]. Not all flaws are expected to impose the same kind of cognitive load, some may even reduce it by cueing the answer, while others introduce confusion that slows examinees down.

When researchers have tested whether IWFs actually affect item performance, the results have been equivocal. Studies examining whether IWFs predict item difficulty or discrimination have reported weak, inconsistent, or null associations [39, 41, 46, 49]. This matters practically as if flaws do not measurably affect how items perform, it becomes hard to justify the cost of detecting and remediating them, and automated detection tools lose their rationale. The problem may not be that flaws are inconsequential but that the standard approach of counting them, treating all 19 criteria as interchangeable contributors to a single "flaw burden" score, masks the signal. Consider that some flaws cue the correct answer, potentially making items faster and easier, while others introduce confusion that slows examinees down and makes items harder. Aggregating these into one count pits opposing effects against each other, producing the attenuated relationships that prior work has observed. The same logic applies to response time, because if cue-giving flaws speed responses and confusion-inducing flaws slow them, a composite IWF count should show a diluted association with processing time, even though specific flaw types carry real cognitive cost. To better guide revision efforts, what is needed is a categorization that separates flaws by what they do to the examinee's response process, so that the distinct (and potentially opposing) mechanisms can be estimated rather than canceled.

We test this hypothesis by categorizing 19 automatically detected item-writing flaws into three cognitive-function categories of cue-giving, confusion-inducing, and structural complexity, and then testing whether this categorization recovers

flaw-outcome relationships that are obscured in aggregate analyses. We analyze 1,230 MCQs bridging the three assessment domains of medical licensure (USMLE, n=653), K-12 mathematics (XES3G5M, n=365), and university computer science (DBE-KT22, n= 212). Each dataset provides item-level mean response time and a difficulty index, allowing us to trace the pathway from flaw presence through processing time to operational difficulty. The cross-domain design tests whether any observed effects reflect a general cognitive mechanism or are specific to a particular testing context. We investigate three research questions:

RQ1: How do item-writing flaw profiles differ across assessment domains?

RQ2: Do the effects of item-writing flaws on response time differ by cognitive-function category and are these effects consistent across domains?

RQ3: Does response time mediate the relationship between item-writing flaws and item difficulty and is this mediation strengthened when flaws are categorized by cognitive-function rather than treated in aggregate?

This study contributes (1) a cognitive-function taxonomy that classifies 19 IWFs into cue-giving, confusion-inducing, and structural complexity categories, revealing that only confusion-inducing flaws impose measurable cognitive cost on examinees, (2) evidence that this confusion effect replicates across three heterogeneous assessment contexts, increasing response time by 14–29% across medical, mathematics, and computer science assessments with no significant domain interactions, and (3) an explanation for why prior aggregate analyses found weak flaw–difficulty relationships. When flaws are categorized, the indirect effect of confusion-inducing flaws through slower response times to higher difficulty is 2.5× the magnitude of the aggregate effect, showing that lumping flaw types together masks the strongest signal.

2. RELATED WORK

2.1 Item-Writing Flaws

Item-writing flaws (IWFs) are features of multiple-choice questions that introduce testwiseness cues, compromise validity, and create unfair advantages for test-takers who recognize these patterns regardless of their actual knowledge [20, 56]. The fundamental concern is that IWFs shift what is being measured from domain knowledge to test-taking skill, introducing construct-irrelevant variance that distorts inferences about examinee ability [12]. Established taxonomies typically use a 19-criterion rubric applicable across subject areas [55, 9]. These capture grammatical or length cues that signal the correct answer, option-set pathologies such as K-type structures, and clarity violations including unfocused or vague question stems [36]. Despite awareness of these standards, IWFs remain prevalent even in professionally developed assessments, with studies finding 36–65% of items flawed in medical education [13, 8, 5] and similar rates in nursing [55], e-learning [9], and STEM disciplines [46, 49]. This persistence has motivated automated detection approaches, including rule-based systems [16] and hybrid systems like the Scalable Automatic Question Usability Evaluation Toolkit (SAQUET) [35]. This system operationalizes the full rubric and has achieved strong agreement with expert raters across diverse domains.

The empirical case that IWFs actually affect item performance is surprisingly weak. Studies in medical education found no consistent relationship between specific flaw types and difficulty or discrimination [41], with similar null results in veterinary [46] and broader STEM assessments [49]. One exception found that flawed items were easier in nursing assessments, but only for specific IWFs rather than the overall count [56]. If IWFs do not measurably affect how items perform, it becomes difficult to justify the cost of detecting and remediating them. However, the problem lies not with the flaws themselves but with how they have been measured.

2.2 The Aggregation Problem

Prior work treats all 19 IWF criteria as interchangeable contributors to a single score, but the rubric encompasses flaws whose cognitive mechanisms theory predicts should operate in opposite directions [8]. Cognitive load theory (CLT) distinguishes intrinsic load, inherent to the assessed content, from extraneous load imposed by how material is presented [10, 44]. In a well-constructed MCQ, the dominant load should be intrinsic as examinees expend effort retrieving and applying domain knowledge. IWFs distort this balance, but the direction of distortion depends on what the flaw does to the response process. Downing [12] drew a parallel distinction at the score level, noting that flawed items produce either construct-irrelevant easiness, which inflates scores, or construct-irrelevant difficulty, which deflates them. For instance, a word repeating between the MCQ's text and answer provides a lexical shortcut that lets test-wise examinees bypass retrieval (construct-irrelevant easiness) [20, 56]. In contrast, an ambiguous stem or gratuitous information forces examinees to infer what is being asked before retrieval can begin (construct-irrelevant difficulty), adding extraneous load [44] on features unrelated to the assessed content. These two classes of flaws should push response time and difficulty in opposite directions.

Aggregating them into a single count pits these opposing effects against each other. An item with one cue-giving flaw and one confusion-inducing flaw registers the same count as an item with two flaws of the same type, despite imposing very different cognitive demands [44]. Across a dataset, this cancellation systematically attenuates observed flaw-outcome relationships, producing exactly the weak or null associations that prior work has reported [41, 46, 39]. What is needed is a categorization that separates flaws by their cognitive function, so that opposing mechanisms can be estimated rather than canceled. This study tests this hypothesis by categorizing the 19 IWFs into three cognitive-function categories and examining whether this categorization recovers flaw-outcome relationships that aggregate analyses obscure.

2.3 Response Time and Difficulty

Response time (RT) has been established as a valuable process measure that captures cognitive processing demands during assessment tasks [40, 26]. Often grounded in CLT [44], RT can help distinguish between productive struggle with

content that supports learning and extraneous cognitive load imposed by irrelevant features that burden working memory [10]. Unlike accuracy alone, which provides only a binary outcome, RT reveals how students interact with items and the degree of cognitive effort required to formulate a response [50, 47]. This temporal signature is particularly valuable for understanding processing burdens imposed by poor item design. Theoretically, questions that introduce unnecessary confusion or complexity should produce characteristically longer processing times [61].

Previous research consistently demonstrates associations between longer RT and higher item difficulty, though the relationship is complex and multifaceted [22]. Multiple factors are known to influence RT beyond content difficulty itself, including the cognitive complexity of required reasoning, linguistic features such as readability and syntactic complexity, and structural characteristics including stem length and number of options [42, 29]. While RT relates to item structure and operational difficulty, it is unclear if RT mediates the relationship between specific quality issues (IWFs) and difficulty outcomes. Existing RT research has focused primarily on prediction rather than diagnosis, modeling overall time-on-task or completion rates without connecting temporal patterns to specific quality deficits that could guide authors in creating higher quality questions [61, 54].

2.4 Automated Item Diagnostics

Traditional psychometric quality control relies on post-hoc approaches such as Item Response Theory (IRT) and Classical Test Theory (CTT) to evaluate item performance [15, 52]. These methods require substantial response data, often hundreds of examinees per item, to produce stable parameter estimates [48]. This means that flawed items have already been deployed and consumed learner time before problematic questions are identified. Operationally, many assessments rely on simpler metrics such as proportion-correct or transformed accuracy indices rather than full IRT parameterization [15]. These have been shown to correlate highly with IRT difficulty estimates and require less extensive calibration data [62]. More fundamentally, both IRT and CTT characterize *what* an item's difficulty is, not *why* it is difficult. Neither framework traces the process pathway from specific design features through cognitive processing to observed outcomes, which is the question motivating the present study. Recent advances in machine learning and artificial intelligence have introduced pre-deployment difficulty prediction methods that leverage linguistic features [7], readability metrics [33], and large language models [3, 14] to estimate item difficulty from text alone. These approaches move closer to identifying difficulty sources before deployment, but they still treat items as isolated text rather than as interactive cognitive tasks, focusing on surface features without modeling the processing demands that items impose [17]. Also, they typically identify which items are likely to be problematic without providing actionable guidance about what specifically should be revised, limiting their utility for iterative quality assurance.

Parallel developments in automated time-on-task estimation and IWF detection have operated in similar isolation. RT estimation methods typically rely on shallow features or aggregate completion patterns without connecting temporal signatures to specific quality issues that create processing burdens [51]. Automated IWF detectors, while effective at flagging rule violations, function as diagnostic checklists rather than risk assessors [16, 35]. They identify the presence of flaws but do not indicate whether those flaws impose meaningful processing costs or distort difficulty in practice. The fundamental gap across these lines of work is the absence of an integrated framework that links flaw patterns to process signatures to operational outcomes. This disconnect becomes especially critical as AI-accelerated item generation scales assessment development, yet still produces MCQs that contain flaws [23, 28], even in standardized exams reviewed by multiple experts [34]. Practitioners need quality signals that are both predictive enough to enable pre-deployment screening and diagnostic enough to guide specific, actionable improvements.

Table 1: Overview characteristics of the three datasets.

	USMLE	DBE-KT22	XES3G5M
Domain	Medicine	Comp. Sci.	Math
N items	653	212	365
N options	4–8	2–5	2–5
Stakes	High	Low	Low
Resp./item	∼300+	458–1,049	5–3,237
RT: M (SD) s	85.6 (29.2)	78.5 (40.8)	197.2 (116.1)
Difficulty	Continuous	Ordinal	Continuous

3. METHODS

3.1 Datasets

We draw on three MCQ datasets spanning different disciplines, examinee populations, and testing contexts to assess whether the relationships between item-writing flaws and item performance generalize beyond a single setting. Our cross-setting comparisons therefore test whether the flaw–RT mechanism replicates across heterogeneous assessment contexts rather than isolating a pure domain effect. Table 1 summarizes the key characteristics of each dataset.

3.1.1 USMLE

The first dataset comprises retired clinical MCQs released by the National Board of Medical Examiners for a shared task on predicting item difficulty and response time [63]. The items are drawn from Steps 1, 2 CK, and 3 of the United States Medical Licensing Examination (USMLE) [37] and were authored by experienced subject-matter experts following guidelines that emphasize a standard MCQ structure. They discourage construct-irrelevant cues such as extraneous material, misleading wording, or correct options that are considerably longer than distractors. We excluded 14 of the 667 MCQs in this dataset for data-quality and format issues, primarily invalid Unicode in the source file or having more than 8 answer options, which the automated IWF evaluator we utilized does not support [35]. This yielded an analytic sample of 653 medical licensure MCQs. Each item was administered to approximately 300 or more examinees on a live high-stakes exam. For every item we observe the mean response time (RT) in seconds, computed from on-screen presentation until the examinee advances past the item, aggregated across all test-takers who encountered the item. We also observe a difficulty index defined as a linearly

transformed proportion correct scaled so that higher values indicate more difficult items.

3.1.2 DBE-KT22

The second dataset is drawn from DBE-KT22, a knowledge-tracing dataset collected between 2018 and 2021 on the CodeBench platform at the Australian National University [1]. It contains MCQs from an undergraduate Relational Databases course attempted by students across disciplines including computer science, engineering, business, and arts. We use all 212 items in the dataset. Each item was answered by between 458 and 1,049 students in a self-paced, low-stakes practice environment. Response time for each item is the mean time in seconds taken by students to submit an answer. Unlike the USMLE's continuous difficulty scale, difficulty in DBE-KT22 is an ordinal rating assigned by the course instructors (1=easy, 2=medium, 3=hard), which we retain as an ordinal outcome in downstream analyses.

3.1.3 XES3G5M

The third dataset originates from XES3G5M, a large-scale knowledge-tracing benchmark of third-grade mathematics exercises collected from an online learning platform operated by TAL Education Group in China [30]. The original items are in Chinese, so we use the English translation produced by Ozyurt et al. [38], who translated the question text via the deep-translate Python library for a related study. Because these items were machine-translated rather than originally authored in English, some detected flaws may partly reflect translation artifacts. However, the flaw–RT relationships in XES3G5M are consistent in direction and magnitude with those observed in the two English-native datasets and the pooled model finds no significant flaw-by-domain interactions (Section 4.2). This suggests that any such artifacts do not differentially drive the results.

From the translated item bank we selected the subset of MCQs for which at least five student responses and their associated timestamps were available, yielding 365 items. We adopt this inclusive threshold to maximize the analytic sample and models for XES3G5M use WLS with $\sqrt{n}$ weights to down-weight less precisely estimated item-level means. Robustness checks excluding items with fewer than 30 and 50 responses confirm that results are not driven by low-n items (Section 4.2). Because XES3G5M does not ship with precomputed item statistics, we derived both variables from the student-level interaction logs. Difficulty is computed as 1 minus the proportion of correct first-attempt responses, so that higher values indicate harder items. Response time for each student-item pair is estimated as the elapsed time between the start timestamp of the given question and the start timestamp of the next question in that student's sequence. These per-student times are then averaged across all students who attempted the item.

3.2 Automated Item-Writing Flaw Detection

We detect item-writing flaws (Table 2) with SAQUET (Scalable Automatic Question Usability Evaluation Toolkit) [1], an open-source and domain-agnostic system that operationalizes the standard 19-criterion IWF rubric to produce both per-flaw binary indicators and a total IWF count per item [35]. SAQUET was designed specifically as a tool to prescreen assessments before they are used with students, to capture testwiseness cues and clarity/alignment violations that introduce construct-irrelevant variance. This includes grammatical or length cues to the key, K-type option structures, negative or vague stems, non-parallel options, overlapping alternatives, and more. Prior work reports that such automated IWF application attains strong agreement with expert raters across diverse domains and that it outperforms readability-style proxies for question quality [35]. In this study we use SAQUET as the automated IWF engine and consume its outputs directly in our analyses. Following SAQUET's pipeline, we normalize Unicode and whitespace, lowercase, and tokenize stems and options before applying a layered set of detectors for the 19 IWF criteria.

We selected SAQUET because it is, to our knowledge, the only open-source tool that operationalizes the full 19-criterion IWF rubric in a domain-agnostic manner and has been used in previous research [49, 6]. Alternative MCQ evaluation systems either cover fewer criteria or are not publicly available [16]. Because SAQUET detects structural patterns rather than directly measuring cognitive disruption, its flags should be understood as indicators of flaw *presence* rather than flaw *impact*. This distinction bears on the interpretation of null results, particularly for cue-giving flaws (see Section 6). SAQUET returns a 19-dimensional binary vector per MCQ and derived aggregates (any-flaw and total IWF count). Full implementation details and previously reported accuracy (exact-match, Hamming loss, per-criterion F1) for this method are documented in prior work [35].

3.3 Flaw Category Taxonomy

The standard 19-criterion rubric [55] encompasses IWFs that should theoretically push examinee processing in opposite directions. We address this by mapping each of the 19 IWFs (described in Table 2) into one of three categories based on the type of cognitive demand the flaw is expected to impose. The mapping, summarized in Table 3, was fixed a priori before any outcome analyses were conducted based on the previous literature review. As outlined in Section 2.2, different IWFs are expected to distort the balance between intrinsic and extraneous cognitive load in opposing directions. We operationalize this distinction by mapping each flaw to one of three categories based on the direction of its expected effect as indicated in prior research.

We adopt three categories because the relevant theoretical distinction for our research questions is the direction of the predicted effect. Confusion-inducing flaws impose extraneous load with a clear directional prediction (↑ RT, ↑ difficulty), grounded in well-replicated effects of ambiguity, negation, and gratuitous information on processing demands [20, 44]. Structural-complexity flaws also alter processing, but the direction is not as predictable, as some (e.g. K-type with one obviously plausible combination) may simplify the task, others (e.g. "all of the above") expand it, and some operate primarily on guessing probabilities rather than RT. Collapsing these into a single extraneous load category would conflate flaws with directional predictions and flaws without, weakening the test the taxonomy is designed to perform. Cue-giving flaws form the third category because they carry the opposite directional prediction (↓ RT, ↓ diffi-

[1] `https://saquet.io/`

Table 2: The 19 Item-Writing Flaw (IWF) rubric criteria used to evaluate multiple-choice questions [55, 35].

Item-Writing Flaw	Description of Flaw
Ambiguous/Unclear	The question text or options contain unclear or ambiguous language
Implausible Distractors	One or more distractors are not plausible to be selected, reducing the effectiveness of the item
None of the Above	A "none of the above" option is included, which primarily tests the ability to detect incorrect answers
Longest Option Correct	The correct option is noticeably longer or more detailed than the distractors, cueing students
Gratuitous Information	The stem contains unnecessary information not required to answer the question
True/False Question	The options are structured as a series of true/false statements
Convergence Cues	Options contain overlapping combinations of components that hint at the correct answer
Logical Cues	The wording contains deductive shortcuts that allow the answer to be derived without domain knowledge
All of the Above	An "all of the above" option is included, allowing students to guess based on partial knowledge
Fill-in-the-Blank	Words are omitted from the middle of the stem for students to insert from the options
Absolute Terms	Absolute terms (e.g. always, never) appear in the options, which students recognize as typically false
Word Repeats	Words or phrases are repeated between the stem and the correct option but not in the distractors
Unfocused Stem	The stem does not present a clear, focused question that can be understood without reading the options
Complex or K-Type	The question requires selecting from combinations of responses rather than a single best answer
Grammatical Cues	Options are not grammatically consistent with the stem or parallel in style and form
Lost Sequence	Options are not arranged in a logical (e.g. chronological or numerical) order
Vague Terms	Vague terms (e.g. frequently, occasionally) are used in the options, whose meaning is subjective
More Than One Correct	The question does not have a single best answer, multiple options could be considered correct
Negative Wording	The stem uses negative wording, which can confuse students and obscure the intended learning outcome

culty), making a three-way structure necessary to represent the full range of theorized effects.

Category A (5 flaws): Cue-giving flaws reduce the effective cognitive work required to reach the correct answer. When a stem repeats a key phrase that appears only in the correct option, or when the correct option is conspicuously longer than the distractors, test-wise examinees can exploit these patterns to bypass the intended retrieval process [56, 20]. The five flaws in this category all share the property of providing a shortcut, such as word repeats creating lexical overlap between stem and key. The longest-answer-correct introduces a length asymmetry and grammatical cues allow elimination based on grammatical inconsistencies between an MCQ's text and options [59]. Convergence cues let overlapping options point toward the key and logical cues embed deductive pathways in the stem or option structure [18]. If these cues function as intended by the IWF literature, they should reduce both response time and difficulty [56].

Category B (6 flaws): Confusion-inducing flaws add processing demands that are extraneous to the assessed construct. An unfocused stem forces the examinee to infer what is being asked before retrieval can begin and ambiguous or unclear language requires re-reading and disambiguation [18]. Relatedly, gratuitous information consumes working memory without contributing to the answer [2]. Lost sequencing disrupts the natural scan order of options and negative wording introduces a reversal demand that is well documented to increase errors and slow responses [20]. Vague terms similarly force examinees to interpret subjective qualifiers rather than evaluate content, such as "usually" or "some". These six flaws share a common mechanism because they impose extraneous cognitive load in the sense of Puma et al. [44], consuming time-limited processing resources on construct-irrelevant features of the MCQ. We therefore predict that confusion-inducing flaws will increase response time and, through this added processing burden, associate with greater difficulty.

Category C (8 flaws): Structural complexity flaws alter the response format or option-set architecture in ways that change the task demands, but without a clear directional prediction. Complex K-type structures (e.g. "A and C", "B, C, and D") require combinatorial evaluation rather than single-best-answer selection, which may increase processing time but could also simplify the task if only one combination is plausible [60]. "None of the above" and "all of the above" options shift the response strategy from selecting the best answer to exhaustively verifying each option [11]. True/false formatting and fill-in-the-blank structures change the fundamental task from recognition to verification or recall [19]. Implausible distractors reduce the effective number of options, which could speed responses by shrinking the choice set or could paradoxically slow them if examinees second-guess why an obviously wrong option was included [4]. Absolute terms ("always", "never") occupy a genuinely ambiguous position as item-writing guidelines flag them because test-wise examinees learn to treat absolutes as likely incorrect [20]. This would place them in Category A, but the terms may also confuse less experienced examinees who take them at face value. We assign absolute terms to Category C to acknowledge this ambiguity. The eight flaws in this category share the property of restructuring the response task itself and we treat their effect direction as an empirical question rather than an a priori prediction.

The opposing predictions for Categories A and B are central to this study. If the taxonomy captures meaningful cognitive distinctions, an aggregate IWF count that collapses across categories should show a diluted effect, while category-level analyses should recover the underlying signals.

3.4 Analysis

For each item, we computed three structural control variables: stem length (word count of the question text), number of options (count of non-null answer choices, ranging from 2–8), and mean option length (average word count across options). From the 19 IWFs, we derived binary category variables indicating the presence of at least one cue-giving, confusion-inducing, or structural complexity flaw, as well as corresponding count variables for dose–response analyses. Response time (the item-level mean across all respondents)

Table 3: Mapping of 19 item-writing flaws to cognitive-function categories based on the expected effect on the examinee response process.

Item-Writing Flaw	Rationale
A: Cue-Giving (predicted: ↓ RT, ↓ difficulty)	
Word Repeats	Shared wording between stem and key lets examinees match rather than retrieve
Longest Ans. Correct	Length asymmetry singles out the key without content evaluation
Grammatical Cues	Agreement mismatches allow elimination of options on form alone
Convergence Cues	Overlapping option content narrows the viable set toward the key
Logical Cues	Deductive structure in the stem or options reveals the answer without domain knowledge
B: Confusion-Inducing (predicted: ↑ RT, ↑ difficulty)	
Ambiguous/Unclear	Unclear language forces examinees to infer intent before engaging content
Unfocused Stem	Absence of a clear question expands the space of plausible interpretations
Gratuitous Info	Irrelevant details load working memory without aiding the response
Lost Sequence	Unordered options disrupt systematic comparison across alternatives
Negative Stem	Negation imposes an additional reversal step during option evaluation
Vague Terms	Subjective qualifiers (e.g., "frequently") require interpretation beyond content
C: Structural Complexity (predicted: direction uncertain)	
Complex/K-Type	Combinatorial format may increase evaluation load or simplify when only one combination is plausible
None of the Above	Shifts task from selecting the best option to exhaustively verifying all options
All of the Above	Shifts task from selecting the best option to exhaustively verifying all options
Fill-in-the-Blank	Recall-oriented format changes the cognitive task from recognition to generation
True/False	Binary format alters baseline difficulty and guessing probability
Absolute Terms	May cue test-wise examinees ("always" = likely false) or confuse naïve ones
Implausible Distractors	Reduces effective choice set, but may also prompt second-guessing
More Than One Correct	Multiple defensible keys change elimination strategy unpredictably

was winsorized at the 1st and 99th percentiles within each dataset and log-transformed to approximate normality [32]. For within-dataset models, log(RT) serves as the outcome, enabling interpretation of coefficients as approximate percent changes in response time. For pooled cross-domain models, both RT and difficulty were z-scored within each dataset prior to concatenation, so that one unit represents one within-dataset standard deviation and cross-domain comparisons reflect relative rather than absolute effects. Difficulty is treated as continuous for USMLE and XES3G5M and as ordinal (1 = easy, 2 = medium, 3 = hard) for DBE-KT22. Because USMLE items were each answered by approximately 300+ examinees (roughly constant), those models use ordinary least squares with HC3-robust standard errors [31]. XES3G5M and DBE-KT22 have variable respondent counts per item (5–3,237 and 458–1,049, respectively), so models for these datasets use weighted least squares with $\sqrt{n}$ weights and HC3-robust standard errors to down-weight less precisely estimated item-level means [24].

To address RQ1, we compared the prevalence of each of the 19 IWFs across datasets using chi-square tests (Fisher's exact where expected cell counts fell below 5), with Benjamini-Hochberg false discovery rate correction ($q = 0.05$) applied across the 19 tests and Cramér's V quantified effect sizes at both the individual-flaw and category levels [21, 57]. For RQ2, we fit within-dataset regressions of log(RT) on the three category indicators and structural controls, followed by a pooled model with domain fixed effects and flaw-category-by-domain interactions to test cross-domain consistency. A non-significant joint Wald test for the interaction terms would support a domain-general mechanism [25]. For RQ3, we used bootstrap mediation [43] (5,000 iterations, bias-corrected and accelerated 95% confidence intervals) to estimate indirect effects of each flaw category on difficulty through response time. The aggregate single-indicator model serves as the baseline against which categorized indirect effects are compared. Mediation was conducted separately for USMLE and XES3G5M (continuous difficulty), pooled with domain fixed effects, and corroborated in DBE-KT22 using ordinal logistic regression in which coefficient attenuation upon adding RT indicates consistency with the mediation pathway. All analyses were conducted in Python using `statsmodels` (OLS/WLS, ordinal logistic, Wald tests) and `scipy` (chi-square, Spearman correlations, bootstrap implementations for mediation inference).

4. RESULTS

The final samples comprised 653 items (USMLE, medical), 365 items (XES3G5M, math), and 212 items (DBE-KT22, computer science), for a pooled 1,230 MCQs. All 19 IWFs were evaluated and detailed in the taxonomy in Table 2. Note that the more-than-one-correct IWF had zero instances across all three datasets and was excluded from all models.

4.1 IWF Profiles Across Domains

The three domains exhibited different flaw profiles in both their composition and prevalence (Table 4). Across all three datasets USMLE was the least flawed, with 64.8% of the MCQs being free of IWFs. DBE-KT22 sat at the opposite extreme, with 93.4% of the MCQs containing at least one flaw and XES3G5M occupied an intermediate position with 58.6% flawed. The datasets also differed in which flaw

Table 4: Flaw prevalence, category distribution, and mutual exclusion group sizes by domain.

	USMLE (Medical)	XES3G5M (Math)	DBE-KT22 (CS)
N items	653	365	212
% with any flaw	35.2%	58.6%	93.4%
Mean IWF count (SD)	0.47 (0.75)	0.99 (1.11)	2.02 (1.22)
% with cue-giving flaw	29.9%	21.1%	39.6%
% with confusion flaw	4.6%	39.2%	41.5%
% with structural flaw	6.1%	17.5%	65.1%
Mutual exclusion groups			
No cue/confusion	440 (67.4%)	178 (48.8%)	70 (33.0%)
Cue only	183 (28.0%)	44 (12.1%)	54 (25.5%)
Confusion only	18 (2.8%)	110 (30.1%)	58 (27.4%)
Both	12 (1.8%)	33 (9.0%)	30 (14.2%)

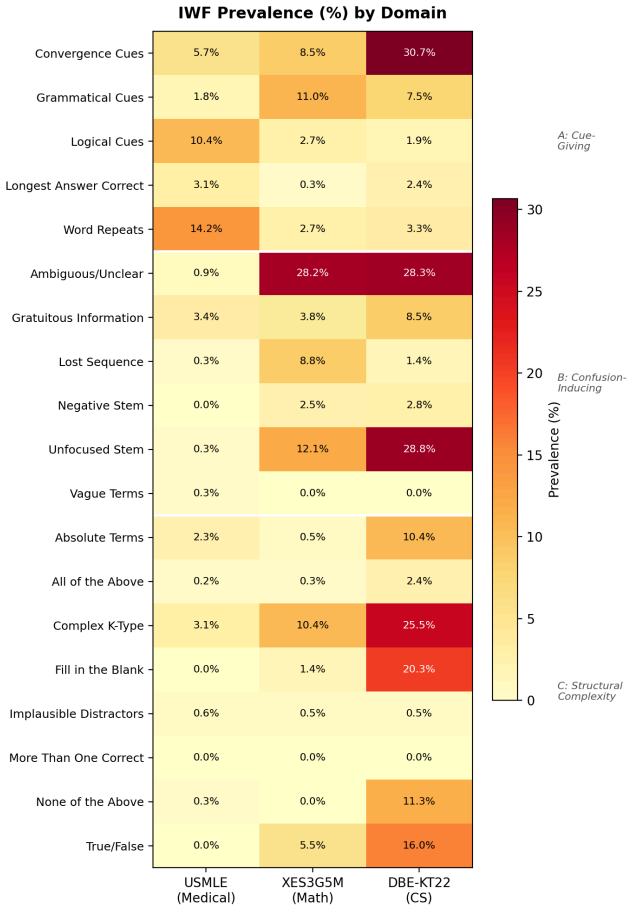

Figure 2: Prevalence of individual item-writing flaws by dataset.

categories dominated. Cue-giving flaws were most common in USMLE, driven by word repeats between stem and key (14.2%) and logical cues (10.4%). Confusion-inducing flaws were rare in USMLE but prevalent in both XES3G5M (39.2%) and DBE-KT22 (41.5%), driven primarily by ambiguous or unclear information (28% in both datasets) and unfocused stems (12.1% in XES3G5M, 28.8% in DBE-KT22). Structural complexity flaws were concentrated in DBE-KT22 (65.1%), where complex K-type items (25.5%), fill-in-the-blank formats (20.3%), and true/false items (16.0%) were common. As shown in Figure 1, when expressed as a share of all detected flaws the category composition of each domain is uniquely different. A majority of USMLE flaws were cue-giving, XES3G5M flaws were confusion-inducing, and DBE-KT22 was more evenly split between confusion and structural complexity.

Chi-square tests comparing each of the 19 IWFs across the three domains, with Benjamini-Hochberg correction for multiple comparisons ($q = 0.05$), found that 16 differed significantly in prevalence (Cramér's $V = 0.085$-0.396), with per-flaw prevalence shown in Figure 2. The three non-significant IWFs, vague terms, implausible distractors, and more-than-one-correct, all had near-zero prevalence in every dataset. At the category level, all three flaw categories differed significantly across domains (all $p < .0001$). The largest effect was for structural complexity ($V = 0.536$), followed by confusion-inducing flaws ($V = 0.433$) and cue-giving flaws ($V = 0.137$). These differences are not merely quantitative, as each domain has a distinct flaw *signature*. USMLE is dominated by cue-giving flaws, XES3G5M by confusion-inducing flaws, and DBE-KT22 by structural complexity. This heterogeneity suggests that treating IWFs as a single aggregate construct risks obscuring domain-specific patterns that may have consequences for examinee performance.

4.2 Item-Writing Flaws and Response Time

Before examining category-level effects, we established the aggregate association between IWF presence and response time. Spearman correlations between total IWF count and mean response time were significant and positive in all three datasets (Table 5). The OLS slopes translate this association into a practical metric of cognitive cost, where each additional detected IWF was associated with roughly 5-16 additional seconds of response time depending on the dataset. That this association holds across all three domains, despite differences in item format, examinee population, and absolute response time scales, establishes a consistent baseline that flawed items take longer to answer. This motivates the subsequent category-level analysis to determine whether this

Table 5: Aggregate association between flaw count and response time. Spearman ρ and OLS slope with 95% CI, all with $p < .001$.

	DBE-KT22	USMLE	XES3G5M
ρ	0.306	0.139	0.214
sec/flaw	+10.45	+4.86	+16.20
95% CI	[6.14, 14.76]	[1.89, 7.82]	[5.54, 26.86]

aggregate signal reflects a uniform contribution from all flaw types or is driven by a specific subset of them.

Within-dataset regression models predicting log(RT) from flaw-category indicators and structural controls revealed a clear asymmetry among flaw categories (Table 6). All models control for z-scored stem length, number of options, and z-scored mean option length, with USMLE estimated via OLS and XES3G5M and DBE-KT22 via WLS ($\sqrt{n}$ weights). Additionally, all use HC3-robust standard errors and coefficients are reported as percent change in RT ($\%\Delta = 100 \times (\exp(\beta) - 1)$). Confusion-inducing flaws were the only category to significantly increase RT, doing so in all three domains (+14-29%, all $p < .05$). A dose-response sensitivity analysis using IWF counts rather than binary indicators confirmed these patterns with the confusion count significant in all three domains ($p = .003$, .010, $< .001$). Cue-giving flaws showed no significant effect on RT in any dataset (all $p > .15$), with coefficients that were positive rather than negative, contrary to the a priori prediction that cue-bearing items would be answered faster. Structural complexity flaws were also non-significant everywhere (all $p > .52$).

A mutual exclusion grouping reinforced these findings as items with only confusion flaws took 16.5-27.0% longer than items free of IWFs. MCQs containing both cue-giving and confusion flaws showed nearly identical RT to the confusion-only group ($\Delta < 2\%$, both $p > .88$ in USMLE and DBE-KT22), indicating that the confusion component drives the effect. These results held across multiple robustness checks that included median RT (confusion significant in XES3G5M and DBE-KT22), unweighted models (all conclusions unchanged), exclusion of low-n items at thresholds of $n \geq 30$ and $n \geq 50$ (confusion $p = .009$ in both), and variance inflation factors below conventional thresholds (all VIFs < 1.5).

The pooled model with IWF-category-by-domain interactions ($R^2 = 0.146$, $N = 1{,}230$) provided a direct test of cross-domain consistency for IWFs increasing RT. The main effect of confusion-inducing flaws was significant ($\beta = +0.516$, $SE = 0.169$, $p = .002$), while the joint Wald test for all six interaction terms was non-significant ($F(6, 1215) = 0.956$, $p = .454$). Per-category interaction tests were also non-significant (cue $\times$ domain: $p = .853$, confusion $\times$ domain: $p = .167$, and structural $\times$ domain: $p = .275$). This pattern of a significant main effect with non-significant interactions supports the interpretation that confusion-inducing flaws impose a processing cost that replicates across these three heterogeneous assessment settings. We found 83-100% of estimable confusion-inducing flaws showed positive RT coefficients across datasets, while most cue-giving flaws did not show the predicted negative direction (20-60% alignment).

Table 6: Flaw category effects on log(RT) from within-dataset regressions, reported as percent change in RT.

Dataset	Cue-giving %Δ (p)	Confusion %Δ (p)	Structural %Δ (p)
USMLE ($N = 653$)	+3.7% (.151)	+14.0% (.016*)	−2.3% (.590)
XES3G5M ($N = 365$)	+15.0% (.233)	+29.4% (.005**)	+7.1% (.524)
DBE-KT22 ($N = 212$)	+8.1% (.295)	+18.9% (.040*)	−3.3% (.676)

4.3 Response Time Mediation of the Flaw-Difficulty Relationship

The aggregate flaw-RT association did not extend to a direct flaw-difficulty link. Spearman correlations between total IWF count and difficulty were non-significant in USMLE and XES3G5M, with only DBE-KT22 showing a reliable association ($\rho = 0.331$, $p < .001$). Meanwhile, the RT-difficulty link varied sharply across datasets, as it was strong in USMLE ($\rho = 0.525$, $p < .001$), moderate in DBE-KT22 ($\rho = 0.245$, $p < .001$), and near-zero in XES3G5M ($\rho = 0.060$, $p = .250$). Total effects of IWFs on difficulty, the direct association without accounting for RT, were non-significant in both datasets, for both the aggregate indicator and all three category-specific indicators (all $p > .18$). With flaws reliably increasing RT, but rarely associating directly with difficulty, mediation analysis is needed to test whether the flaw signal transmits *through* response time even when the direct path is negligible.

Formal mediation was conducted on USMLE and XES3G5M, which have continuous difficulty measures (Figure 3). Using 5,000 bootstrap iterations with bias-corrected confidence intervals, the aggregate indirect effect was modest in USMLE (+0.093) and non-significant in XES3G5M (+0.019). Categorizing by cognitive function revealed that the USMLE aggregate was driven almost entirely by the confusion pathway, as the confusion-inducing indirect effect (+0.231) was the only category to reach significance and was 2.5 times the aggregate magnitude. Cue-giving (+0.064) and structural (−0.040) indirect effects were non-significant. In XES3G5M, all category-specific indirect effects were non-significant, consistent with the weak RT-difficulty link in that dataset. The USMLE results also exhibited a suppression pattern as the positive indirect effect through RT coexisted with a near-zero total effect (total effect = −0.024) because the direct effect was negative (direct effect = −0.243 for confusion). This specifically indicates that the indirect and direct paths operate in opposing directions. The pooled model ($N = 1{,}018$, USMLE + XES3G5M with domain fixed effects) strengthened these findings. Both confusion (+0.117) and cue-giving (+0.051) indirect effects reached significance, with confusion roughly 2.3 times the cue-giving effect. Domain interaction terms were non-significant on both the flaw-to-RT and flaw-to-difficulty equations (both $p > .41$), supporting domain-general mediation.

In DBE-KT22 ($N = 212$), where difficulty is an instructor-assigned ordinal label, formal mediation is not applicable. Instead we tested whether adding RT to an ordinal logistic regression attenuated flaw-difficulty associations. Without

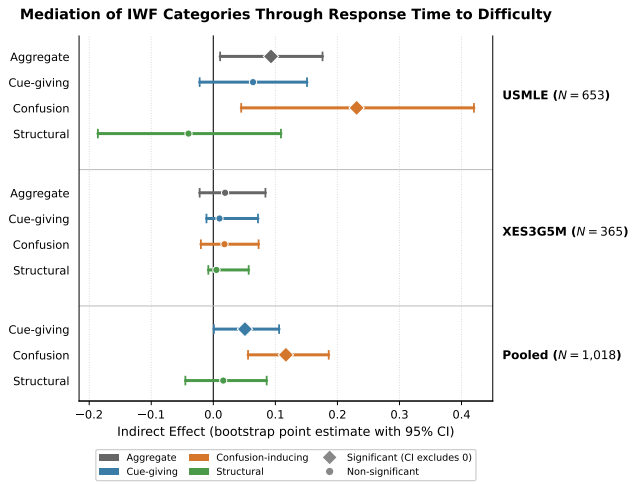

Figure 3: Bootstrap indirect effects (point estimates with 95% bias-corrected CIs) for the flaw category → RT → difficulty mediation pathway. All models control for stem length, option length, and number of options.

RT, both confusion ($\beta = +1.418$, $p < .001$) and structural ($\beta = +1.536$, $p < .001$) flaws predicted higher difficulty ratings. Adding log(RT) improved model fit (LR $\chi^2 = 12.85$, $p = .0003$) and attenuated the confusion coefficient by 10.3%, consistent with partial mediation through RT. Structural flaw coefficients showed no attenuation, suggesting their link to instructor-judged difficulty operates through other channels.

5. DISCUSSION

This study set out to test whether the inconsistent relationships between item-writing flaws with response time and difficulty reported in prior work [41, 46, 49, 39] reflect a measurement problem rather than a null effect. Across 1,230 items from three assessment domains we found that IWF profiles differ qualitatively, with each exhibiting a distinct signature rather than simply more or fewer flaws. When these flaws are categorized by their expected cognitive function, confusion-inducing flaws emerge as the sole category that imposes measurable processing cost, increasing response time by 14-29% across all three domains with no significant domain interactions. This processing cost transmits to difficulty where the RT-difficulty link is strong. In the medical MCQ dataset from the USMLE, the confusion-mediated indirect effect is 2.5 times the aggregate and the pooled model confirms confusion as the dominant pathway. The aggregate flaw-difficulty relationship is weak not because flaws do not matter, but because lumping cue-giving, confusion-inducing, and structural flaws into a single count dilutes the one category that carries the signal.

The domain specific IWF profiles are interpretable in light of each assessment's development context. USMLE's low flaw rate and cue-giving dominance is consistent with a professionally developed high-stakes exam where item writers follow established guidelines, but occasionally allow subtler cue-giving flaws (word repeats, logical cues) to persist [5]. DBE-KT22's saturation with structural complexity and confusion inducing flaws reflects the reality of instructor-authored items in a university CS course, where formal item-writing training is likely minimal [18]. XES3G5M's distinctive confusion profile, 39% of items flagged, driven by ambiguous stems and unfocused questions, may reflect the particular challenge of writing unambiguous items for younger learners in mathematics [27]. These domain specific signatures matter because they determine which category level effects will dominate in any given assessment context. A medical MCQ with one cue-giving flaw and a computer science MCQ with one confusion flaw both register identically under an aggregate count. However, our results show they carry fundamentally different cognitive consequences. Treating flaws as a monolithic construct, as prior work has largely done, obscures this heterogeneity and motivates the category-level analyses we conducted.

Our central finding is that confusion-inducing IWFs (ambiguous or unclear information, unfocused stems, gratuitous details, lost sequencing, and negative wording) are the active ingredient behind the aggregate flaw-RT association. Adding 5 to 16 additional seconds per IWF is carried entirely by the confusion-inducing category. Cue-giving flaws did not reduce RT in any dataset, contrary to the prediction from cognitive load theory and the IWF literature that they should speed responses by signaling the correct answer [56, 20]. Several explanations may account for this null result. SAQUET may detect structural patterns such as word overlap or length asymmetry that do not function as usable cues for examinees under time pressure. Cue-giving flaws may also co-occur with item properties that increase complexity, such as longer stems or more technical language, offsetting any facilitation. Alternatively, the cueing effect may operate on accuracy rather than speed, where examinees who would otherwise guess may benefit from the cue but not necessarily arrive at the answer faster [45]. This may be particularly if recognizing and exploiting the cue requires its own processing effort. Regardless of the cue-giving null, the confusion effect itself is robust across domains. Non-significant interaction terms (Wald $p = .454$) indicate that confusion-inducing flaws impose a comparable relative processing cost across these three datasets. However, since each domain is represented by a single dataset, we cannot disentangle domain from these co-varying factors. This consistency of the effect across such heterogeneous contexts is consistent with a construct-irrelevant processing burden, extraneous processing load in the language of cognitive load theory [44], that is independent of the domain knowledge being assessed.

The mediation results complete the chain from IWF presence through processing time to operational difficulty, while also revealing an informative boundary condition. In USMLE, where RT and difficulty are strongly linked ($\rho = .525$), the confusion-inducing indirect effect was 2.5 times the aggregate, revealing a mediation pathway that aggregation dilutes. In XES3G5M, confusion flaws still increased RT, but RT did not associate with difficulty ($\rho = .060$) and mediation was accordingly null. This divergence is informative rather than problematic as it suggests that what "difficulty" captures varies across assessment contexts. In USMLE, difficulty tracks closely with processing time where harder items take longer. In XES3G5M, difficulty may instead reflect conceptual barriers, such as misunderstanding the underly-

ing mathematics, that do not manifest as additional processing time. A student who lacks the requisite knowledge may answer quickly and incorrectly, producing high difficulty without elevated RT. This dataset dependence helps explain why prior work treating flaws in aggregate across single datasets has found weak or null flaw–difficulty relationships [41, 46]. Those studies conflated flaw types with different (or null) indirect effects and did not account for variation in how strongly aspects like RT track to difficulty. DBE-KT22 provides corroborative evidence from a third operationalization of difficulty. The confusion coefficients attenuated 10.3% when RT was added to an ordinal logistic model of instructor-assigned difficulty ratings, while structural flaw coefficients showed no attenuation. The differential attenuation pattern reinforces the category distinction where confusion flaws operate partly through response time and structural flaws reach difficulty through other channels. This may be through visible format features that instructors associate with complexity when assigning ratings. Together, these results indicate that categorization by cognitive function can help provide insight into the mechanism through which IWFs affect examinee performance.

There are interpretive caveats related to resposne time, as longer resposne time can reflect productive engagement, extraneous load, or sources unrelated to either. This makes it challenging to directly observe cognitive load at the item level. In this work, we treat the additional 14–29% response time under confusion-inducing flaws as cognitive cost because the flaws are by construction construct-irrelevant, but this is an inference from design rather than direct measurement. Additionally, the association of response time translating to performance harm depends on assessment context. In timed high-stakes tests, examinee time is bounded and per-item delays compound into real consequences for completion. In low-stakes practice the throughput cost is less acute, and the primary harm of confusion-inducing flaws may be to the construct validity rather than to performance directly. The XES3G5M boundary case, where confusion flaws increased RT but RT did not associate with difficulty, is consistent with this distinction.

The practical implication is that item quality improvement efforts should prioritize confusion-inducing flaws that create ambiguity, unfocused stems, and gratuitous information because these are the flaws that impose measurable cognitive cost on examinees. Cue-giving flaws remain a concern for validity if they inflate scores, and structural flaws may matter for format standardization, but neither category affects response time in our data. Because the confusion effect is domain general, this recommendation does not require adaptation for specific domains. The guidance to eliminate ambiguity and sharpen stem focus applies equally to medical licensure exams, K-12 math assessments, and university CS courses. For automated detection tools like SAQUET [35] or related ones [16], these findings suggest that not all flags deserve equal weight. A confusion-inducing IWF should trigger revision priority over a cue-giving flag when the goal is reducing construct-irrelevant cognitive load and saving examinee time. More broadly, the results argue for moving beyond binary "flawed or not" classifications toward taxonomies that distinguish flaws by their cognitive consequences. This approach may prove fruitful for both item quality assurance and for understanding how assessment design shapes examinee behavior. The 5-16 additional seconds per flaw documented in our analysis is a real cost, but attributing it equally to all IWFs misidentifies the source and therefore misdirects the remedy.

6. LIMITATIONS AND FUTURE WORK

Several design constraints temper the conclusions drawn here. All analyses operate at the item level using mean response times aggregated across respondents, which precludes examining within-person effects or distinguishing processing patterns, such as fast-correct versus slow-incorrect responses. The flaw indicators themselves are structural pattern matches produced by an automated detector, not ground-truth judgments of cognitive disruption. This distinction may partly account for the cue-giving null, if SAQUET flags formal patterns (e.g. word overlap) that do not function as usable cues under real testing conditions. DBE-KT22's small zero-flaw baseline ($n = 14$) increases estimator variance for that dataset, though the regression framework does not require a large joint-zero group in the same way ANOVA would. USMLE lacks median response time data, so the median-RT robustness check could not be applied to the dataset with the strongest mediation finding. While the three datasets used spanned unique domains, they also varied in examinee population, authoring practices, and more, which also attribute to the observed differences. Finally, although we use the language of mediation throughout, the design is observational and cross-sectional at the item level. These indirect effects should be interpreted as associational pathways rather than confirmed causal chains.

Student-level analysis with individual response times would permit testing whether confusion-inducing flaws impose uniform processing costs or disproportionately burden lower-ability examinees, a question the item-level design cannot address. Examining whether cue-giving flaws affect accuracy rather than speed would test the alternative interpretation that cueing operates on correctness without reducing response time. The taxonomy could also be applied to AI-generated items to determine whether large language models produce different flaw signatures than human item writers, a question of growing practical relevance as automated item generation scales. More broadly, the RT-based screening approach demonstrated here could be formalized into a practical quality assurance tool with decision thresholds that weight confusion flags above other flaw types, moving from the associational evidence presented in this study toward an actionable pre-deployment diagnostic.

7. CONCLUSION

Across 1,230 multiple-choice questions from three assessment domains, we show that weak or inconsistent relationships between item-writing flaws and item outcomes are often a measurement consequence of aggregation, not evidence that flaws are inconsequential. By introducing a cognitive-function taxonomy that separates cue-giving, confusion-inducing, and structural-complexity flaws, we reveal that different flaw types operate through distinct mechanisms, so collapsing them into a single flaw count can mask real effects. In particular, confusion-inducing flaws are the primary driver of processing burden, increasing mean response time by 14-29% across domains, an effect that held across

all three domains without significant moderation. When difficulty covaries with response time, the added time burden from confusion-inducing flaws is consistent with an indirect pathway to higher operational difficulty via response time. In the USMLE dataset, this indirect effect is 2.5× larger than the indirect effect based on the aggregate flaw count. For assessment practice, the implication is that not all IWFs deserve equal attention. Automated evaluation tools become more useful when they prioritize confusion-related issues, such as gratuitous information, that reliably add time due to wording rather than the target skill. As AI-generated assessment content scales, the taxonomy introduced here provides a cognitively grounded framework for quality assurance that moves beyond simply flagging flaws, to prioritizing the ones that impose measurable time costs on examinees and distort what assessments measure.

The Semantic Gap in Behavioral Embeddings: Why Linear Methods Fail for Educational RAG in Mathematics

ABSTRACT

Educational AI systems often assume that behavioral failure patterns in student data reveal latent semantic structures useful for tutoring. We rigorously audit this assumption using 15.8 million student interactions from UK secondary mathematics. By correlating a 50-dimensional SVD-based behavioral manifold with neural semantic embeddings across 1,869 questions, we identify a critical **Semantic Gap**: a near-zero correlation ($r = 0.000$) demonstrating that behavioral patterns are functionally independent of semantic content. This gap causes systematic Topical Drift in naive RAG systems, where behavioral-only retrieval performs below random chance (12.3% pairwise win rate). To bridge this gap, we introduce the principle of **Semantic Primacy** and a hybrid **Manifold-Augmented Generation (MAG)** architecture. Our results show that MAG achieves superior diagnostic specificity (4.78/5) compared to zero-shot baselines by enforcing semantic filtering before behavioral personalization. Finally, we characterize the **Semantic Opacity** of behavioral clusters through expert audit, proving the necessity of architectural integration over manual curation. This work establishes a new baseline for understanding behavioral-semantic orthogonality in educational data mining.

Educational Data Mining, Retrieval-Augmented Generation, Behavioral Patterns, Semantic Embeddings, Matrix Factorization, Educational AI

1. INTRODUCTION

Educational AI systems currently face a profound grounding problem. While foundation models generate pedagogically plausible responses, they often lack *diagnostic specificity*, leaving them unable to adaptively guide learners through different cognitive states such as confusion, partial understanding, and misconception [8]. This blindness leads to a reliance on linguistic patterns rather than pedagogical ones. Recent work has turned to behavioral manifolds: clustering questions by how students fail to reveal diagnostic structures invisible to semantic analysis [17]. The hypothesis is compelling: if students make identical errors across different problems, those problems likely share a behavioral attractor, a latent misconception that transcends the wording of the prompt in question.

Recent systematic evaluations [8] expose the depth of this diagnostic blindness and demonstrate that foundation models fail to perceive learner states accurately, to orchestrate appropriate instructional strategies, and to elicit reflection when students exhibit surface-level correctness while harboring fundamental misconceptions. A model might validate a student who correctly applies the quadratic formula yet cannot explain why the discriminant determines the number of solutions. This creates a pedagogical hazard: students receive affirmation for brittle knowledge that crumbles under transfer. The issue is not linguistic coherence but diagnostic precision. Without grounding in actual student failure patterns, even the most eloquent model remains pedagogically shallow.

However, this behavioral manifold hypothesis rests on an untested assumption of alignment. Do interaction patterns from student responses preserve the semantic coherence necessary for retrieval in agentic teaming? If behavioral clustering merely captures difficulty levels or generic test-taking patterns rather than conceptual relationships, systems using these patterns will retrieve topically irrelevant context. This Topical Drift undermines the agent's reliability, creating a mismatch where a student struggling with negative numbers receives hints about fractions simply because both show similar failure rates.

In this work, we rigorously audit the prevailing architectural standard of linear embeddings. While non-linear techniques are emerging, the vast majority of scalable educational platforms default to linear methods like SVD-based matrix factorization for real-time recommendation due to their computational frugality and interpretability. This focus on linear methods is not arbitrary. Singular Value Decomposition (SVD) based approaches dominate real-time educational platforms precisely because they provide the computational speed required for responsive tutoring at scale. Platforms serving millions of students require sub-second response times for hint generation and content sequencing. SVD decomposes sparse interaction matrices into low-dimensional representations that enable rapid

nearest-neighbor search without expensive recomputation.

Intelligent tutoring systems, adaptive learning platforms, and recommendation engines from Khan Academy to Carnegie Learning rely on variants of this approach. Given this
widespread deployment, auditing the semantic fidelity of linear behavioral embeddings directly impacts the pedagogical quality experienced by students daily. If these methods systematically fail to preserve topic coherence, millions of learners receive contextually inappropriate feedback through architectures designed for efficiency rather than semantic grounding. We treat these methods as the empirical baseline to investigate the following research questions (**RQs**):

- **RQ1:** Do linear projections of binary correctness preserve semantic similarity when measured against modern neural embeddings?
- **RQ2:** What are the practical consequences of semantic-behavioral orthogonality for retrieval-based tutoring systems?
- **RQ3:** Can architectural integration, such as Manifold-Augmented Generation (MAG), leverage orthogonal signals to outperform high compute zero-shot models?
- **RQ4:** Do behavioral patterns exhibit Semantic Opacity, rendering them unreadable to human experts and necessitating computational stabilization?

Using a massive dataset of 15.8 million student interactions from UK secondary mathematics, we construct a 50-dimensional behavioral manifold via SVD. This finding implies that Behavioral Sightedness and Semantic Understanding are orthogonal dimensions of the learning experience. We demonstrate that this gap leads to systematic failure in naive retrieval systems, where behavioral-only retrieval frequently retrieves topically irrelevant hints. However, we propose that this independence is a design opportunity rather than a defect.

By enforcing **Semantic Primacy**, a hybrid architecture that filters by topic before personalizing by behavior, we can leverage these orthogonal signals to catch invisible errors that linguistic models miss. Finally, we bridge the gap between data mining and the learning sciences through a qualitative *Expert Tagging* study to evaluate whether these manifolds represent human-readable pedagogical traps. This work advances what we term the Sighted-Frugal paradigm.

Rather than pursuing diagnostic precision through ever larger foundation models, we demonstrate that architectural constraint can achieve superior specificity at a fraction of the computational cost. The prevailing assumption in educational AI has been that pedagogical failures stem from insufficient model capacity. This fuels an arms race toward parameter scaling, where each generation of models grows more expensive to train and deploy. We challenge this assumption. Our results show that a modest model like GPT-4o-mini, when augmented with properly structured behavioral context, outperforms far larger zero-shot alternatives in diagnostic tasks. The key is not scale but grounding.

By respecting the orthogonality between behavioral and semantic dimensions, we can build systems that are simultaneously more accurate and more accessible. This matters for equity. Computationally intensive models concentrate educational innovation in well resourced institutions. Sighted-Frugal architectures democratize access to diagnostic AI.

Our primary contributions are as follows:

1. **Quantification of the Semantic Gap:** We provide the first large-scale empirical evidence that linear behavioral embeddings common in deployed systems are functionally independent of semantic content, providing a theoretical ceiling for naive RAG systems.
2. **The Principle of Semantic Primacy:** We establish a core design requirement for educational RAG: systems must strictly filter by semantic content before applying behavioral personalization to avoid pedagogical drift.
3. **Demonstration of Sighted-Frugal AI:** We validate a hybrid Manifold-Augmented Generation (MAG) architecture that outperforms high compute zero-shot models in diagnostic specificity, offering a path toward more equitable and sustainable educational AI.

2. RELATED WORK

2.1 Behavioral Data for Misconception Detection

Mathematics education research has long argued that effective instruction requires identifying systematic error patterns rather than mere correctness [9]. Cognitive evidence suggests that these behavioral signatures reflect underlying conceptual structures [2]. Recent large-scale efforts, such as the Eedi dataset [3] and diagnostic benchmarks from Wang et al. [17], have enabled the computational mining of these misconceptions.

The Gap: While these works provide the raw material for diagnostic AI, they often assume that behavioral clusters are inherently semantically meaningful. Our work explores and tests this assumption by auditing whether the clusters discovered in these datasets actually align with the conceptual categories recognized by expert educators and semantic models.

2.2 Knowledge Tracing and Interaction Modeling

Knowledge Tracing (KT) has evolved from Bayesian frameworks [4] to deep recurrent architectures such as RNNs [11] capable of predicting student mastery from high-dimensional interaction logs.

The Gap: These models are traditionally optimized for *predictive performance* (i.e., will a student get the next problem right?). However, being able to predict a failure does not necessarily mean the model understands the semantic

nature of that failure. Thus, we aim to move beyond prediction to investigate whether the latent spaces created by KT-like interaction modeling are sufficiently grounded in content to support *retrieval and generation* in tutoring applications, specifically for mathematics-based coursework.

2.3 Retrieval-Augmented Generation (RAG) in Education

RAG systems improve generation by retrieving external context based on semantic similarity [7, 13]. In education, this has roots in retrieving worked examples for Cognitive Tutors [14] and early automated hint generation from historical data [1].

The Gap: Standard educational RAG assumes that semantic similarity (how a problem is worded) is the best proxy for retrieval. Conversely, behavioral systems assume that failure patterns are the best proxy. To our knowledge, no prior study has measured the *alignment* between these two signals. We identify the Semantic Gap between these dimensions, necessitating the shift toward our proposed *Semantic Primacy* architecture.

2.4 Model Alignment and Diagnostic Precision

General-purpose foundation models are aligned for helpfulness and safety using techniques like RLHF [10] and DPO [12]. However, recent evaluations show that this alignment often lacks *diagnostic specificity*, causing models to provide polite but pedagogically vague feedback [8].

The Gap: Effective feedback requires precision [5], yet models often fall into a Black Box of Competence. We investigate whether incorporating behavioral manifolds as retrieval context can provide the Sightedness necessary to restore diagnostic precision without the heavy compute costs of model retraining.

2.5 Triangulated Evaluation Methodologies

The rise of LLM-as-a-Judge [18] has enabled scalable evaluation, but educational contexts require more rigorous, multi-dimensional validation to ensure replicability and improved metacognition [15].

The Pivot: We avoid reliance on a single metric by employing a triangulated methodology. We combine automated neural scoring with a qualitative Expert Tagging component to test for *Semantic Opacity*. This ensures that our findings are grounded not just in statistical correlation, but in pedagogical reality.

3. METHODOLOGY

3.1 Data Sources and Problem Formulation

We utilize the NeurIPS 2020 Education Challenge dataset [17], comprising 15.8 million interactions from the Eedi platform (UK secondary mathematics, ages 11-18). To ground our behavioral manifold in expert pedagogy, we cross-reference this with the 2024 Mining Misconceptions dataset [3], which provides expert-verified labels for common student errors.

From an initial pool of 27,613 questions, we isolated a core set of 1,869 questions with expert labels. For our comparative agentic experiments, we focused on 242 questions that met the threshold for high diagnostic utility: a minimum of 500 student interactions and a failure rate of at least 40%. This subset was divided into a development set ($n = 120$) and a held-out evaluation set ($n = 122$).

3.2 Auditing the Behavioral Manifold (SVD)

To represent the industry standard for scalable educational AI, we constructed a behavioral manifold using (SVD). We generated a sparse binary interaction matrix M, where $M_{i,j} = 1$ denotes a correct response from student i to question j.

We reduced this matrix to a 50-dimensional space, capturing the latent patterns of student success and failure. While modern deep learning techniques exist, we intentionally selected SVD to audit the specific linear assumptions prevalent in real-time production systems. To identify structural attractors within this space, we applied spectral clustering [16] with a nearest-neighbors affinity graph (n=10), identifying $k = 50$ clusters. This choice was based on domain considerations rather than optimization, though silhouette analysis yielded a score of -0.050, reflecting the pedagogically realistic property that trap clusters are not geometrically isolated from the broader manifold. Behavioral coherence was instead validated through downstream cluster statistics: identified trap clusters exhibited consistent failure rates and substantial interaction volumes, confirming that spectral clustering captured psychometric structure rather than geometric separation.

We prioritized pedagogical interpretability over statistical optimization: clusters with clean separation (high silhouette scores) but mixed difficulty profiles would be computationally elegant yet pedagogically meaningless. Our resulting clusters exhibited behavioral coherence, questions within each cluster shared similar failure rates and discrimination parameters, validating that spectral clustering captured psychometric structure rather than random noise. Critically, this behavioral coherence did not translate to semantic coherence, as subsequent correlation analysis would reveal.

While alternative cluster counts were not systematically explored, the resulting structure proved pedagogically interpretable: identified trap clusters exhibited consistent failure rates (40 to 51 percent) and substantial interaction volumes (1000 plus interactions per question), while mastery clusters demonstrated clear success patterns (success rates exceeding 70 percent). This behavioral coherence, despite the lack of formal hyperparameter tuning, suggests the clustering captured meaningful pedagogical structure rather than statistical noise.

3.3 Quantifying the Semantic Gap

To measure the alignment between behavior and content, we computed semantic embeddings for all questions using Sentence-BERT (S-BERT) [13]. We validated that these 384-dimensional vectors captured pedagogical relationships (e.g., questions with identical misconception labels showed significantly higher cosine similarity, $p < 0.001$).

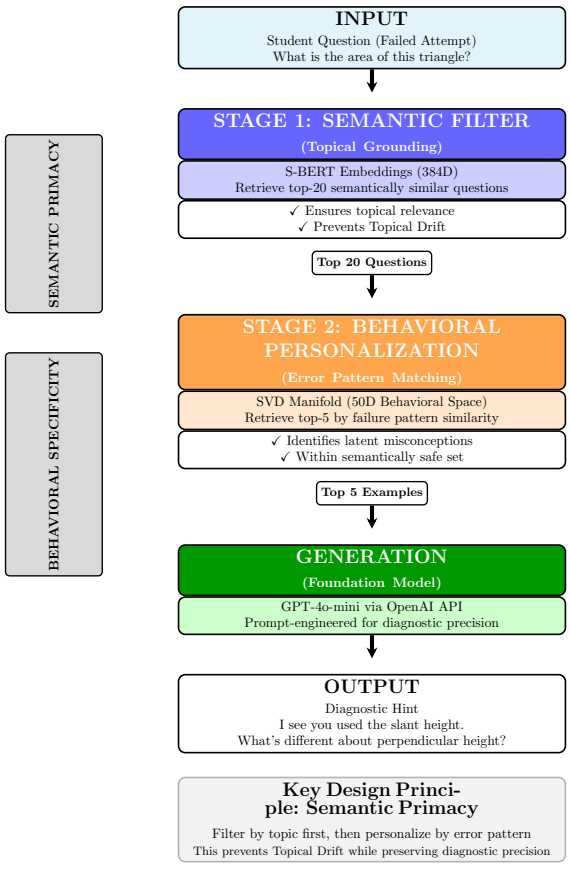

Figure 1: MAG architecture implementing Semantic Primacy. The pipeline enforces a two-stage constraint: semantic filtering narrows retrieval to topically relevant questions (top 20), then behavioral personalization identifies error patterns within this semantically bounded set (top 5). This sequential design prevents topical drift while preserving diagnostic specificity. Generation employs GPT-4o-mini via API with prompt engineering for pedagogical precision. Comparative evaluation (n=122) demonstrated that this architectural approach (4.75/5) substantially outperforms DPO-aligned Llama-3-8B (2.96/5, $p<0.001$), validating that architectural constraint on capable models dominates explicit alignment of smaller alternatives.

The Semantic Gap was measured by calculating the correlation between behavioral similarity (computed as $1/(1+d)$ where d is the Euclidean distance in the 50D SVD space) and semantic similarity (cosine similarity in the 384D Sentence-BERT space). We employed Pearson's r, Spearman's ρ, and permutation testing to ensure that the observed independence was not a result of difficulty-based confounds.

This operationalization requires explicit justification. Euclidean distance in the SVD-reduced space represents the standard metric for behavioral nearest neighbor search in production recommendation systems: it directly measures the dissimilarity used by retrieval algorithms when selecting contextually similar problems. Cosine similarity in neural embedding space serves as our semantic proxy because S-BERT explicitly optimizes for sentence-level semantic similarity, and we validated that it captures pedagogical relationships (questions sharing misconception labels show significantly higher similarity). The correlation between these distance measures tests whether behavioral neighborhoods preserve semantic structure: if they did, questions close in behavioral space would also be close semantically, yielding positive correlation. Our near-zero result indicates behavioral proximity provides no semantic information.

3.4 Agentic Architectures and Semantic Primacy

We compared four tutoring architectures to evaluate how different retrieval strategies impact the Sightedness of the agent. All systems utilized GPT-4o-mini as the generation backbone throughout, ensuring that differences in performance were attributable solely to the retrieval logic. GPT-4o was used exclusively as the evaluation judge for System D (see Section 3.5), not as a generator in any system.

- **System A (Zero-Shot):** A high compute baseline using GPT-4o-mini without external context, representing the ungrounded generation.
- **System B (Semantic RAG):** A standard RAG approach that retrieves the five most topically similar questions

based on S-BERT embeddings.

- **System C (Behavioral RAG):** A behavior-only approach that retrieves the nearest neighbor in the 50D SVD space, testing if failure patterns alone provide sufficient diagnostic context. This single-neighbor retrieval reflects how behavioral-only systems operate in practice, and tests whether even minimal behavioral context provides diagnostic value.
- **System D (MAG: Semantic Primacy):** Our proposed hybrid architecture. It operates via a two-stage **Filter-then-Personalize** process:
    1. **Semantic Filter:** The system identifies the top 20 most topically relevant questions across the dataset.
    2. **Behavioral Personalization:** Within this semantically safe subset, the system selects the top 5 questions nearest in distance within the behavioral manifold.

3.5 Evaluation and Pedagogical Constraint

Ensuring diagnostic precision requires pedagogical guardrails that prevent common failure modes such as false validation, shallow feedback, or premature solution revelation. We employed carefully engineered prompts that emphasize conceptual scaffolding and diagnostic specificity. All systems used identical prompt templates, ensuring that performance differences could be attributed solely to retrieval strategy rather than linguistic variation in generation.

Beyond prompt engineering, we investigated whether preference learning could offer complementary benefits. We fine-tuned Llama-3-8B-Instruct using Direct Preference Optimization (DPO) [12] with 600 contrastive pairs constructed from 120 anchor questions. Each anchor generated five preference pairs corresponding to distinct pedagogical boundaries: politeness bias (empty affirmation masking diagnostic gaps), shallow diagnosis (symptom labeling without mechanistic explanation), geometric imprecision (conflating structurally adjacent misconceptions), premature answer-giving (violating the Zone of Proximal Development), and technical opacity (exposing retrieval mechanics to learners). Training employed LoRA adapters [6] (r=16, α=32) over three epochs, explicitly teaching rejection boundaries through contrastive supervision. Rejected responses were systematically constructed to violate each pedagogical boundary: for politeness bias, rejected hints provided affirmation without diagnostic reasoning; for shallow diagnosis, they identified error symptoms without mechanistic explanation; for answer-giving, they revealed solutions rather than scaffolding discovery. Chosen responses demonstrated diagnostic precision aligned with each boundary constraint.

Comparative evaluation across all 122 test questions yielded a decisive result: the preference-aligned model achieved 2.96/5 quality, significantly trailing GPT-4o-mini within the MAG architecture (4.75/5[1], Δ = -1.79, $p < 0.001$). Across 122 pairwise comparisons, the DPO model never outperformed the baseline (0% win rate). This empirical outcome validates a central tenet of the Sighted-Frugal paradigm: architectural constraint applied to capable foundation models dominates explicit alignment of smaller alternatives. The performance gap suggests that model capacity and structured retrieval provide greater pedagogical leverage than parameter-efficient supervision signals, at least within the scale regime tested here.

Final evaluation employed triangulated measurement:

1. **Automated Scoring:** Hint quality was evaluated on a five-point diagnostic scale across 122 questions using GPT-4o as judge for System D and GPT-4o-mini as judge for baseline systems A, B, and C. Statistical robustness was ensured through 10,000 bootstrap resamples, yielding confidence intervals for all effect sizes.
2. **False Validation Detection:** A rule-based classifier flagged instances of inappropriate praise, where systems validated incorrect student reasoning. This provided an objective safety check independent of neural evaluation.
3. **Expert Audit:** Two mathematics educators with secondary teaching experience evaluated cluster interpretability (Semantic Opacity) and pedagogical utility of generated hints. Inter-rater reliability metrics (Cohen's κ, ICC) quantified alignment between computational and human assessments.

3.6 Reproducibility

This study is designed for full replication. We used publicly available datasets: the NeurIPS 2020 Education Challenge (15.8 million interactions) and Eedi Mining Misconceptions (expert-labeled questions). Our pipeline implements standard techniques with documented parameters: 50-component SVD for the behavioral manifold, spectral clustering with nearest-neighbors affinity (n=10, k=50), and Sentence-BERT embeddings (all-MiniLM-L6-v2, 384 dimensions). The MAG architecture performs two-stage retrieval (top-20 semantic, top-5 behavioral) with clearly specified similarity thresholds. We will release complete code, including SVD construction, clustering, RAG implementation, and evaluation protocols, via GitHub at `https://github.com/Rickygole/semantic-gap-educational-rag`.

4. RESULTS

4.1 The Semantic Gap: Quantifying Orthogonality

Our primary analysis across 1,869 expert-labeled questions confirms the existence of the **Semantic Gap**: a state of functional independence between how students fail and what a problem says. As shown in Figure 2, we observed a near-zero correlation between behavioral similarity and semantic similarity (Pearson $r \approx 0.000$, 95% CI $[-0.002, 0.001]$, $p = 0.861$; Spearman $\rho = -0.002$, $p = 0.004$).

[1]The MAG baseline score in this DPO comparison (4.75) is from a matched evaluation pass conducted alongside DPO scoring under identical judging conditions. The 4.78 reported in Table 1 is from the four-system tournament run. The 0.03 difference reflects run-to-run variance from generation at temperature 0.7 across separate API calls.

Figure 2: The Semantic Gap

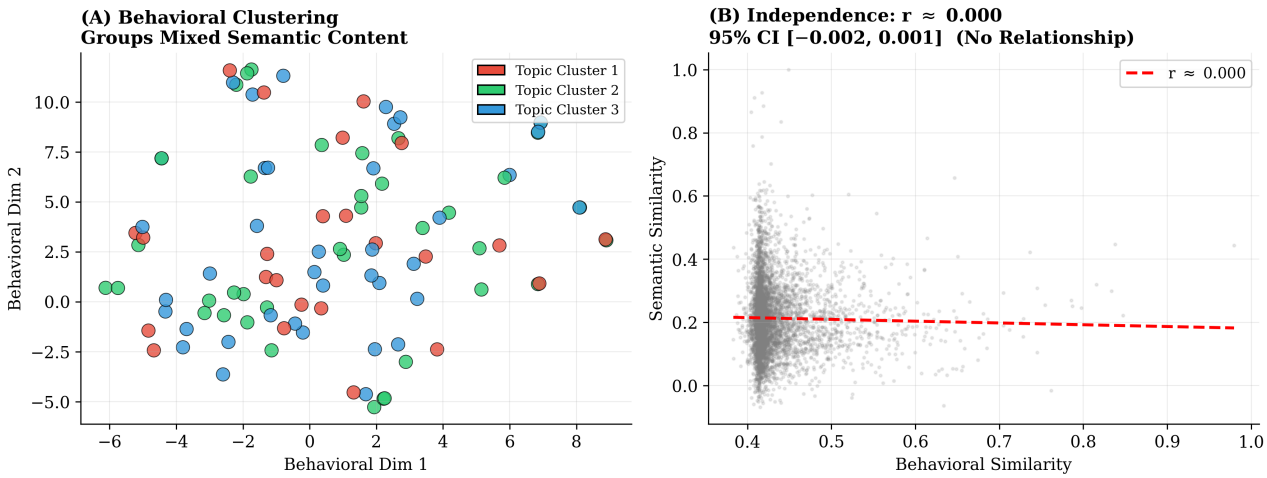

Figure 2: The Semantic Gap: Empirical independence between behavioral and semantic dimensions. Left: Behavioral clustering via t-SNE projection shows questions with mixed semantic content (colors represent different mathematical topics) scattered throughout behavioral space, demonstrating lack of semantic coherence within behavioral neighborhoods. Right: Near-zero correlation r ≈ 0.000, 95% CI [−0.002, 0.001] between behavioral similarity (Euclidean distance in 50D SVD space) and semantic similarity (Sentence-BERT cosine). The flat regression line demonstrates that linear projections of binary correctness are functionally independent to semantic structure required for content retrieval.

Permutation testing (1000 iterations) confirmed that this correlation falls entirely within the null distribution ($p = 0.872$). This near-zero correlation has direct retrieval consequences. Even weak positive correlation (r = 0.2 to 0.3) would allow behavioral signals to improve precision: most neighbors would fall within the correct semantic domain. Near-zero correlation means behavioral proximity provides no information about semantic relevance. A retrieved question is no more likely to be topically related than random selection. Worse, behavioral retrieval operates deterministically rather than randomly, systematically selecting off-topic problems with similar difficulty profiles. This transforms neutral noise into structured misdirection: students receive confident, detailed hints about the wrong mathematical domain.

We ruled out difficulty confounds through stratified analysis on 433 questions meeting high utility criteria (500+ interactions, 40%+ failure rate). Correlations remained near zero within difficulty tertiles: easy items (r = −0.02), moderate items (r = −0.01), and challenging items (r = 0.01). The Gap persists independent of psychometric difficulty. Stratified analysis confirmed that the Semantic Gap persists independently of psychometric item difficulty across all tertiles. Even within tightly constrained problem families such as triangle area calculations, behavioral clustering scattered questions across the manifold based on difficulty rather than geometric properties.

This suggests the Gap reflects a fundamental limitation of binary correctness signals rather than an artifact of aggregating heterogeneous content.

Interpretation: This visualization demonstrates that behavioral neighborhoods are semantically heterogeneous. A student's failure pattern on a Negative Numbers question may be behaviorally identical to their failure on a Fractions question. Knowing the *behavioral attractor* (how they failed) provides zero information regarding the *semantic content* (what they were failing at). This confirms our hypothesis that LLMs are behaviorally blind and SVD manifolds are semantically opaque.

4.2 Systemic Deficits and the Semantic Primacy Rescue

The practical consequences of this Gap are substantial for naive retrieval systems. As detailed in Table 1, System C (Behavioral Retrieval) achieved a pairwise win rate of only 12.3% falling below the 33.3% random baseline for a four-system pairwise tournament ($p < 0.001$). This failure is driven by *Topical Drift*: retrieving behaviorally similar but topically irrelevant context. Consider a diagnostic example from our evaluation set. When presented with a student struggling to subtract negative integers, System C retrieved a question about simplifying algebraic fractions. The only shared attribute was a 52 percent failure rate. The behavioral manifold correctly identified both as difficult items requiring procedural precision, yet this psychometric similarity provided zero pedagogical value.

The student received worked examples about fraction manipulation when they needed conceptual grounding in the number line. System D, by contrast, first filtered to arithmetic operations involving integers, then selected behaviorally similar problems within that semantic boundary. The resulting hint addressed sign confusion in subtraction, a structurally analogous trap within the correct mathematical domain. This contrast illustrates how Topical Drift trans-

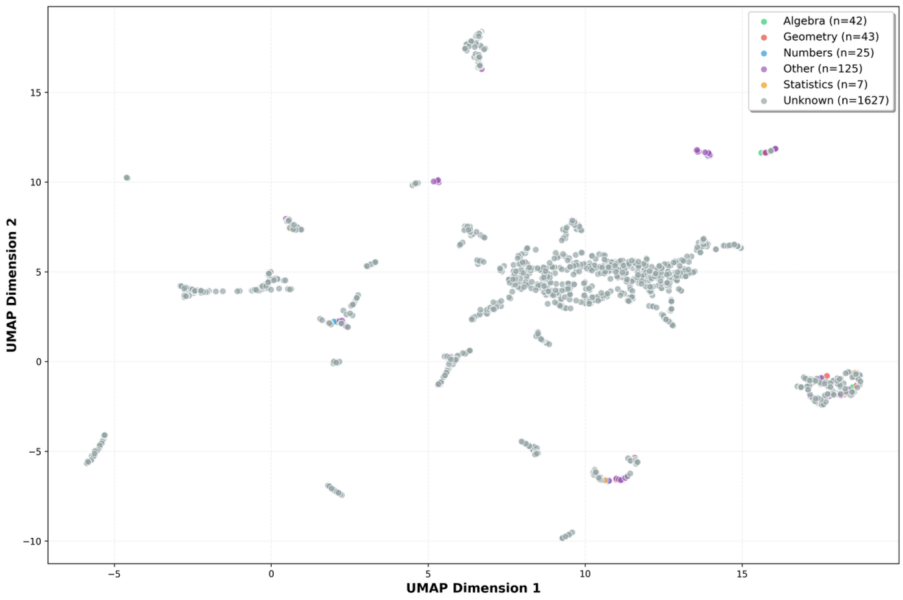

Figure 3: UMAP projection of behavioral space colored by semantic topic. Mathematical concepts (geometry, algebra, number operations, statistics) appear scattered across behavioral clusters rather than grouped, providing visual confirmation that behavioral neighborhoods lack semantic coherence. This dispersion pattern supports our quantitative finding of near-zero correlation between behavioral and semantic similarity.

Table 1: System Performance with Bootstrap Confidence Intervals (10,000 iterations)

Architecture	Quality (1-5)	Std. Dev.	Win Rate
System D: MAG (Hybrid)	**4.78 [4.69, 4.86]**	**0.49**	**49.2%**
System A: Zero-shot (GPT-4o-mini)	4.27 [4.06, 4.47]	1.18	32.5%
System B: Semantic RAG	3.94 [3.74, 4.15]	1.16	24.0%
System C: Behavioral RAG	3.36 [3.13, 3.60]	1.32	12.3%

[†]Win rate computed as pairwise tournament score: fraction of head-to-head comparisons each system wins against each of the three other systems (n=122 questions).

forms behavioral patterns from diagnostic signals into pedagogical noise.

However, our **Semantic Primacy** architecture (System D) successfully bridged this gap. By first filtering for topical relevance and then personalizing via the behavioral manifold, MAG achieved the highest quality (4.78/5) with the lowest variance ($\sigma = 0.49$). MAG demonstrates substantial improvements with effect sizes of d = 0.560 versus zero-shot ($p < 0.001$), d = 0.935 versus semantic RAG ($p < 0.001$), and d = 1.421 versus behavioral RAG ($p < 0.001$). These medium to large effects confirm that architectural integration of orthogonal signals yields measurable gains in diagnostic precision. Prompt sensitivity analysis across 30 test cases verified that behavioral RAG's deficit persists regardless of prompt engineering, isolating topical drift as the causal mechanism rather than suboptimal instruction design.

4.3 Semantic Opacity: The Human-in-the-Loop Barrier

Qualitative audit by two mathematics educators revealed that the behavioral manifold exhibits high **Semantic Opacity**. While the manifold identifies statistically robust clusters, human experts struggled to assign them consistent pedagogical labels (Cohen's $\kappa = 0.40$). Furthermore, inter-rater reliability on the quality of behaviorally-derived hints was poor ($ICC = -0.25$).

Consider Question 514 as a concrete illustration. Students solving a triangle area problem systematically substituted slant height for perpendicular height, a dimensional confusion sharing behavioral signatures with other problems involving oblique versus orthogonal measurements. Semantic RAG retrieved topically proximate geometry questions, yet failed to surface this specific error pattern. The behavioral manifold, however, identified structurally analogous traps across disparate topics. When constrained by semantic filtering, this behavioral signal elevated hint quality by 2.0 points on our diagnostic scale, revealing misconceptions that pure linguistic similarity missed entirely. The structural trap here is subtle. Students treating slant height as equivalent to perpendicular height are not making a calculation error but a dimensional category error. They fail to recognize that area formulas require measurements orthogonal to the base, not measurements along an oblique edge.

This confusion appears across multiple geometric contexts: using hypotenuse length in right triangle area calculations, applying diagonal measurements in rectangle problems, or substituting arc length for radius in circular sectors. Semantic RAG cannot detect this pattern because the questions use different vocabulary and geometric shapes. The

behavioral manifold, however, identifies the shared failure signature: students systematically choose the most visually salient measurement rather than the geometrically appropriate one. This is precisely the kind of latent misconception that benefits from computational detection paired with semantic constraint.

This finding suggests that student failure patterns contain latent traps that are mathematically detectable but pedagogically non-obvious. This necessitates the **computational stabilization** provided by our MAG architecture: rather than asking teachers to curate these clusters, we use semantic embeddings to ground the behavioral signal in human-readable content.

5. DISCUSSION AND LIMITATIONS

5.1 The Semantic Gap as a Structural Property

Our central finding identifies a fundamental structural reality: linear behavioral embeddings derived from binary correctness are functionally independent of semantic content. We argue that this **Semantic Gap** is not a temporary engineering hurdle that can be solved with more data or refined clustering; rather, it is an intrinsic property of what these representations capture.

Linear methods like SVD extract variance from correctness matrices that primarily reflect psychometric properties: item difficulty, student discrimination, and test-taking behaviors (e.g., fatigue or guessing). While these patterns are robust, they do not encode semantic relationships. A question on negative numbers and a question on fractions may share a behavioral attractor due to identical failure rates, but they possess zero conceptual overlap. This explains the substantial deficit of behavioral-only retrieval (12.3% pairwise win rate): the system lacks a mechanism to distinguish between a shared difficulty level and a shared concept. The 50-dimensional SVD space can be understood through the lens of classical test theory.

Each dimension likely corresponds to latent factors governing item response patterns: the first few dimensions capture global difficulty (analogous to the b-parameter in Item Response Theory), subsequent dimensions encode discrimination power (the a-parameter, measuring how sharply performance separates high and low ability students), and later dimensions reflect guessing patterns and test-taking strategies. However, these psychometric constructs are domain-agnostic. A dimension encoding requires multi-step reasoning applies equally to fraction division and quadratic factoring, collapsing conceptually distinct topics into a single behavioral signature. This is why behavioral distance preserves psychometric structure but destroys semantic boundaries.

The manifold encodes how hard questions are, not what they are about. This psychometric-semantic decoupling has profound implications for educational data mining. Traditional approaches to content recommendation implicitly assume that behavioral signals contain topic information that students who struggle similarly are struggling with similar concepts. Our findings falsify this assumption. The behavioral

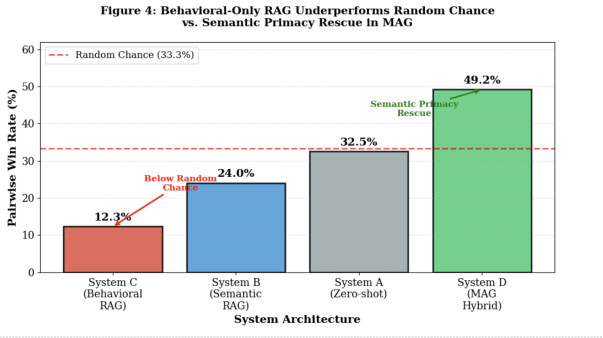

Figure 4: System performance across retrieval architectures. Behavioral-only retrieval (System C) achieves a 12.3 percent pairwise win rate, falling below the 33.3 percent random baseline (dashed line). MAG (System D) reaches 49.2 percent by enforcing semantic filtering before behavioral personalization, demonstrating that architectural constraint on orthogonal signals yields superior diagnostic quality. Win rate computed as pairwise tournament score across 122 evaluation questions.

manifold captures a parallel dimension of the learning experience: not conceptual understanding, but cognitive load, procedural complexity, and metacognitive demand. These are pedagogically valuable signals, but only when grounded within semantic boundaries.

5.2 Semantic Primacy: A Restorative Design Principle

The success of our hybrid MAG model (4.78/5) establishes **Semantic Primacy** as a core design principle for educational RAG. Our results prove that systems must strictly filter by semantic content before applying behavioral personalization. Attempting to learn semantics from interaction patterns alone is a category error that leads to *Topical Drift*.

This principle offers immediate practical value for Frugal AI deployment. It allows developers to leverage behavioral data where it is strongest identifying specific failure modes within a topic while relying on semantic embeddings for what they do best: grounding the conversation in the correct mathematical domain. The independence we discovered is thus not a bug, but a feature that can be exploited through deliberate architectural constraint. The computational efficiency of this approach has direct equity implications. GPT-4o-mini operates at roughly one-tenth the inference cost of GPT-4o while achieving superior diagnostic performance when augmented with behavioral context. This cost differential is not academic.

In under-resourced educational settings where per-student budgets constrain technology adoption, the difference between 10 cents and 1 cent per interaction determines whether AI tutoring is feasible at scale. Sighted-Frugal architectures that combine modest models with structured data enable equitable access to diagnostic AI. The alternative, pursuing diagnostic precision through ever-larger foundation models, concentrates educational innovation in wealthy institutions while leaving resource-constrained schools reliant on generic

chatbots. Our results demonstrate that architectural intelligence can substitute for parameter scale, democratizing access to pedagogically grounded AI.

5.3 Semantic Opacity and the Necessity of Computation

The observed **Semantic Opacity** ($ICC = -0.25$) indicates that the patterns captured by the behavioral manifold are human-unreadable. Because these patterns reflect psychometric variance rather than pedagogical categories, human educators cannot reliably recognize them through traditional pedagogical intuition.

This finding necessitates a shift in how we approach a Human-in-the-Loop design. Manual curation of behavioral clusters is likely infeasible. Instead, we must use computational stabilization like the MAG architecture to translate these opaque behavioral signals into semantically grounded, pedagogically useful hints. This bridges the gap between high-dimensional data mining and the practical needs of the classroom. This *Semantic Opacity* finding reframes the role of AI in educational systems. Rather than replacing teacher judgment, computational methods should function as translators between statistical patterns and pedagogical action.

Teachers cannot intuitively recognize that a triangle area problem shares behavioral signatures with cylinder volume calculations, yet the manifold detects this structural analogy through shared error patterns. The AI does not make pedagogical decisions but surfaces hidden relationships for human interpretation. This positions the system as an augmentation tool rather than an autonomous agent, a distinction critical for teacher trust and adoption. The design implication is clear: behavioral insights must always be presented within semantic containers that educators can evaluate and override.

5.4 Boundaries of the Linear Baseline

As a rigorous audit, this study is bounded by its focus on **Linear Methods** and **Binary Correctness**. While SVD is the industry standard for scalable systems, it represents the empirical baseline rather than the theoretical ceiling. It remains an open and vital question whether nonlinear techniques such as Variational Autoencoders (VAEs), Graph Neural Networks (GNNs), or Attention Mechanisms could bridge the Semantic Gap that linear methods cannot.

Furthermore, our use of binary correctness provides a "maximally impoverished" input. Future work should investigate if richer behavioral signals, such as response latencies, multi-attempt sequences, or option-choice analysis, might preserve semantic structure even under linear projection. Finally, while our dataset of 15.8 million interactions provides significant power, it is situated within the UK secondary mathematics curriculum. Cross-context replication is essential to determine if the Semantic Gap fluctuates across different cultures, age groups, or domains.

5.5 Methodological Reflection and Triangulation

We acknowledge the limitations inherent in using "LLM-as-a-Judge" to evaluate hint quality. System D was evaluated using GPT-4o while baseline systems were evaluated using GPT-4o-mini. We further acknowledge that the behavioral space (50D SVD) and semantic space (384D Sentence-BERT) use different underlying geometries, though both are transformed into comparable similarity measures before correlation; this choice does not affect our near-zero correlation finding, which holds across Pearson, Spearman, and permutation testing. To mitigate evaluation circularity, we employed a triangulated evaluation strategy, incorporating educator audits and rule-based classifiers to detect false validation. While these measures provide a robust signal for diagnostic specificity, definitive claims regarding student learning outcomes will require future longitudinal deployment studies in live classrooms.

By identifying the *Semantic Gap*, we provide a theoretical and practical framework for the next generation of educational AI. We have shown that the Sightedness required for effective tutoring does not come from larger models, but from architectures that respect the independence of behavior and semantics. By enforcing Semantic Primacy, we can move toward a Sighted-Frugal AI that is pedagogically precise, computationally efficient, and ethically grounded.

6. CONCLUSION

This paper identifies and quantifies the **Semantic Gap**: a state of empirical independence between student interaction patterns and semantic content. Through an audit of 15.8 million interactions, we demonstrated that while linear behavioral embeddings are functionally blind to topic, they capture robust psychometric properties that define how students struggle.

We proved that this Gap leads to systematic failure in naive RAG systems, which succumb to *Topical Drift* when retrieving based on behavioral signals alone. However, we have established a restorative design principle: **Semantic Primacy**. By enforcing a hybrid architecture that filters by topic before personalizing by behavior, our **Manifold-Augmented Generation (MAG)** system outperforms even high-compute zero-shot models in diagnostic specificity.

Our discovery of **Semantic Opacity** further suggests that behavioral data contains latent traps invisible to human pedagogical intuition, necessitating the computational stabilization provided by our MAG architecture. Ultimately, this work provides the first large-scale baseline for understanding the relationship between student behavior and content semantics. By respecting the independence structure of educational data, we can move toward a new generation of AI tutors that are not just linguistically fluent, but diagnostically sighted, computationally frugal, and pedagogically just.

7. FUTURE DIRECTIONS

While this study establishes a rigorous linear baseline, it opens several critical avenues for the evolution of Sighted-Frugal AI. We highlight four directions that we believe warrant systematic investigation by the research community.

Future research should investigate whether nonlinear archi-

tectures such as Variational Autoencoders (VAEs), Graph Neural Networks (GNNs), or Attention Mechanisms can bridge the Semantic Gap that linear methods cannot. Graph Neural Networks appear particularly promising given the relational structure of educational data. A message-passing architecture where nodes represent questions, edges encode co-occurrence in student trajectories, and node features combine behavioral statistics with semantic embeddings could learn joint representations. Specifically, a Graph Attention Network (GAT) with multi-head attention could weight connections by both behavioral similarity (questions students fail together) and semantic proximity (questions sharing misconception labels), potentially discovering hybrid distances that respect both dimensions. The question is whether such architectures can learn the Semantic Primacy constraint implicitly or whether architectural enforcement remains necessary.

We utilized binary correctness as a "maximally impoverished" input. Testing whether the inclusion of response latencies, multi-attempt sequences, and process traces can close the Gap even under linear projection remains a vital open question. Specific process signals merit investigation: response latency distributions (whether students pause before errors, suggesting confusion versus rapid incorrect attempts suggesting procedural errors), edit patterns (whether students erase and rewrite, indicating metacognitive awareness), attempt sequences (whether retry strategies differ across misconceptions), and navigation paths (whether students seek help resources differentially by trap type). These temporal and behavioral traces may encode semantic information absent from binary outcomes. For instance, students who pause extensively before answering geometry questions incorrectly may be struggling with visualization rather than calculation, a distinction invisible to correctness alone but potentially detectable through interaction timing.

Mapping the Semantic Gap across diverse domains, age groups, and cultural curricula will determine if this orthogonality is a universal property of educational data or a curriculum-specific phenomenon. Cross-context replication is essential to establish the generality of our findings beyond UK secondary mathematics.

Transitioning from automated quality metrics to longitudinal classroom studies is essential to measure how Semantic Primacy impacts actual skill acquisition and misconception resolution. A feasible deployment protocol would involve a randomized controlled trial in middle school algebra classrooms over one academic semester. Students in the treatment condition would receive MAG-generated hints when struggling with linear equations and systems of equations, while control students would receive standard computer-based practice with generic feedback. Pre and post assessments measuring both procedural fluency and conceptual understanding would quantify learning gains. Critically, the study would track misconception persistence: whether students who receive geometrically grounded hints demonstrate faster resolution of specific error patterns (e.g., sign errors in equation solving, confusion between solutions and equations) compared to controls. Implementation would require integration with existing learning management systems to ensure ecological validity and teacher buy-in.

Finally, larger educator cohorts from several distinct domains, particularly social sciences, humanities, and computer science education, would further probe *Semantic Opacity* and support the development of interfaces that help experts interpret and engage productively with behavioral manifolds.

ABSTRACT

Knowledge Tracing (KT) models are essential for estimating student knowledge states, yet prominent attention-based architectures like SAINT and SAKT struggle with length extrapolation, often failing when sequence lengths exceed those seen during training. This limitation frequently arises from the use of absolute learnable positional embeddings. Furthermore, existing methods often treat interactions as uniformly spaced, failing to capture the continuous temporal dynamics of learning and forgetting. This paper investigates the incorporation of Time-and-Order rotation Positional Encoding (TO-RoPE), which treats both discrete interaction order and continuous real time as geometric properties of the latent space. By applying deterministic rotations to queries and keys, TO-RoPE allows for robust extrapolation to longer sequences while capturing heterogeneous temporal patterns. We conducted an empirical study across three datasets: ASSISTments2017, EdNet, and a Proprietary Dataset. The results demonstrate that replacing absolute embeddings with TO-RoPE significantly improves the AUC performance of SAINT and SAKT in extrapolated windows of up to 500 interactions. In particular, the SAINT + TOR configuration consistently outperformed the baselines, suggesting that explicit geometric modeling of continuous time is a viable approach to modeling long-range dependencies in digital education environments.

1. INTRODUCTION

The aim of personalized education at scale is fundamentally based on our ability to model learners' evolving cognitive states [30]. Knowledge Tracing (KT), the computational task of predicting student future performance based on historical interactions, serves as the analytical engine for personalized solutions, such as Intelligent Tutoring Systems (ITS) and Adaptive Systems [2, 16]. By accurately mapping a student's mastery over specific Knowledge Components (KCs), these systems can transition from static, one-size-fits-all curricula to adaptive environments that provide targeted feedback and optimized learning paths. Furthermore, educational platforms have begun to generate large volumes of data on student interactions, opening opportunities for analytical techniques to enhance the learning experience [23, 11, 3].

In this context, recent breakthroughs in Deep Learning, particularly with Transformer-based architectures such as SAINT and SAKT, have established new benchmarks in KT by using self-attention to capture complex dependencies across student histories [8, 9, 19]. However, these models share a structural dependency on absolute positional embeddings, which treat student interactions as a rigid, equidistant sequence. This approach fundamentally ignores the temporal reality of human learning, in which the time between interactions carries essential information about memory consolidation, interference from external activities, and the inevitable decay of knowledge [28]. Although previous efforts like AKT and LefoKT introduced temporal biases or handcrafted decay functions to mitigate this, they largely treat time as a discrete proxy rather than a continuous intrinsic property of the learning process [14, 5].

On the other hand, the reliance on absolute positions further restricts the models' capacity for length extrapolation. In typical research settings, KT models are trained and validated in truncated interaction windows [2]. However, a truly effective KT system is expected to maintain predictive stability throughout a student's entire academic tenure [13]. As a result, rather than the technical challenge of process-

ing longer sequences, length extrapolation is required for reliable long-term performance predictions [17]. That is, if the predictive accuracy of a model degrades simply because a student has exceeded the interaction count seen during the training phase, the system becomes an unreliable guide for high-stakes longitudinal outcomes, such as identifying early risks of course failure or certifying long-term retention [30].

To bridge this gap, this study investigates a new approach to positional and temporal encoding by integrating Time-and-Order rotation Positional Encoding (TO-RoPE) [27]. By encoding positions as relative rotations in a complex-valued latent space, TO-RoPE provides a theoretically grounded mechanism for both length extrapolation and continuous-time modeling. Unlike additive embeddings, which anchor the model to a fixed coordinate system, rotation encodings allow the attention mechanism to perceive the distance between interactions, both in terms of sequential order and in terms of actual time elapsed, as a relative geometric property. This potentially enables models trained on short interaction windows to generalize seamlessly to the much longer sequences characteristic of real-world educational data.

Therefore, this work evaluates whether substituting absolute embeddings with a dimension-separated TO-RoPE strategy can enhance the robustness of attention-based KT models. To this end, we developed new versions of the SAINT and SAKT architectures to isolate the effects of this geometric encoding and subject them to a rigorous train-short, test-long protocol. Thus, our main contribution lies in demonstrating how this approach affects the extrapolation of student mastery over extended periods and across varying temporal scales. By validating our findings across three diverse datasets, ranging from controlled mathematics tutoring (ASSISTments2017 [4]) to large-scale TOEIC preparation (EdNet [10]) and a proprietary higher-education dataset, we provide evidence for a more scalable and temporally aware framework for KT.

2. BACKGROUND

The KT problem is formally defined as a sequence-processing task aimed at modeling dependencies between past interactions of a student to predict future performance [30, 16]. Given an interaction history:

$$H_{t-1} = \{(q_1, a_1, \tau_1), \ldots, (q_{t-1}, a_{t-1}, \tau_{t-1})\}, \quad (1)$$

where q_i represents the question, $a_i \in \{0, 1\}$ the correctness, and τ_i the timestamp, KT models estimate the probability of correctness for a future question q_t:

$$P(a_t = 1 \mid q_t, H_{t-1}). \quad (2)$$

These estimates are fundamental for adaptive educational systems [2].

2.1 Attention-based Knowledge Tracing

The introduction of the self-attention mechanism [25] revolutionized KT by enabling modeling of long-range dependencies without the vanishing gradient limitations of recurrent neural networks (RNNs), such as deep knowledge tracking (DKT) [21].

Pandey et al. [19] pioneered this approach with Self-Attentive Knowledge Tracing (SAKT), an encoder-only architecture in which the current exercise serves as a query to retrieve relevant past interactions. Subsequently, Choi et al. [9] proposed SAINT, a Transformer-based encoder-decoder model that processes exercises and responses separately.

However, both SAKT and SAINT rely on learnable absolute positional embeddings to encode interaction order. In SAINT, for instance, position is handled by adding a learned vector $\mathbf{P}_i$ to the input:

$$\mathbf{E}_i = \mathbf{kc}_i + \mathbf{q}_i + \mathbf{p}_i. \quad (3)$$

A critical limitation of this approach is the lack of length extrapolation. Since $\mathbf{P}_i$ is learned for specific indices $i \in [0, L_{train}]$, these models fail to generalize when a student's history exceeds the duration of the training window L_{train}, which is a frequent scenario on lifelong learning platforms. Consequently, when $t > L_{train}$, the model lacks a defined positional representation, leading to performance degradation.

2.2 Time-aware Knowledge Tracing

To address the irregularity of learning sessions, several works have incorporated temporal information into attention mechanisms. Ghosh et al. [14] proposed Attentive Knowledge Tracing (AKT), which introduces a monotonic attention mechanism with exponential decay. This method modulates attention weights based on the temporal distance between interactions, reflecting the cognitive effect of forgetting.

More recently, Bai et al. [5] introduced LefoKT, which employs a *relative forgetting attention* mechanism. LefoKT adds a bias term $B_{i,j}$ to the attention logits, penalizing older interactions:

$$\text{Score}(i, j) = \frac{Q_i K_j^\top}{\sqrt{D_k}} + B_{i,j}. \quad (4)$$

Although AKT and LefoKT successfully incorporate temporal biases, they treat time primarily as a scalar penalty (a decay factor or additive bias) applied to the attention scores. This approach imposes an explicit monotonic decay, restricting their capacity to capture complex temporal dynamics, such as non-monotonic forgetting patterns and study periodicity. Furthermore, these models often still anchor their notion of time in discrete ordinal indices.

2.3 Geometric Positional Encodings

To overcome the limitations of absolute embeddings and scalar biases, recent advances in Large Language Models (LLMs) have explored encoding position directly into the geometry of the latent space. Rotating positional *embedding* (RoPE) [22] proposes that the inner product between a query and a key should depend only on their relative distance. Instead of adding a positional vector, RoPE rotates the affine-transformed word embeddings by an angle proportional to their position.

This rotation ensures that the attention score $QK^\top$ naturally captures relative distances, allowing the model to generalize to sequence lengths significantly larger than those seen during training (length extrapolation).

Wei et al. [27] extended this concept to irregular time series with *Time-and-Order RoPE* (TO-RoPE). Recognizing

that discrete order is insufficient for processes with irregular intervals, TO-RoPE treats both discrete order (i) and continuous time (τ) as sources of rotation. By interpolating these two dimensions, the model encodes the *distance* between interactions as a composite geometric property in a complex vector space.

To the best of our knowledge, the integration of Time-and-Order RoPE into the Knowledge Tracing domain remains unexplored. Although existing models like AKT and LefoKT address temporal dynamics through decay mechanisms, they do not leverage the geometric properties of the latent space to model continuous time. This work bridges this gap by replacing absolute positional embeddings in SAKT and SAINT with TO-RoPE, hypothesizing that treating both order and time as rotational components will unlock superior length extrapolation capabilities and more robust temporal modeling.

2.4 Research Questions

As detailed in Section 2, current Knowledge Tracing architectures face a fundamental structural dichotomy: they either rely on absolute positional embeddings that bind the model to fixed sequence lengths (as in SAINT and SAKT) or attempt to patch temporal dynamics through decay mechanisms or additive scalar biases (as in AKT and LefoKT). However, these methods treat time predominantly as an auxiliary bias rather than an intrinsic, continuous dimension of the latent space. In this work, we propose shifting the modeling paradigm from additive embeddings to *Time-and-Order rotation Positional Encoding* (TO-ROPE), postulating that encoding both sequence order and continuous elapsed time as geometric rotations offers a superior inductive bias. To validate this hypothesis, we investigate two critical dimensions of model performance: the capacity for length generalization and the interpretability of learned temporal patterns.

A primary failure of absolute positional embeddings, as described in Section 2.1, is the use of fixed training windows. Because position vectors are learned for specific indices ($i \in [0, L_{train}]$), standard models lack a defined representation of student histories that exceed the window size observed during training—a scenario inherent to lifelong learning platforms. We investigate whether replacing this fixed coordinate system with relative rotation encodings allows the model to decouple predictive capability from absolute positions, thereby maintaining stability over indefinitely long sequences. As such, the first research question is:

> **Research Question 1 (RQ1):**
> *To what extent does replacing absolute positional embeddings with Time-and-Order RoPE enable attention-based Knowledge Tracing models to extrapolate predictive performance to sequence lengths significantly exceeding those observed during training?*

Furthermore, although previous work explicitly enforces temporal forgetting via monotonic decay biases (Section 2.2), it remains unclear whether a model can naturally learn these dynamics solely from geometric constraints. By treating continuous time as a rotational dimension in the complex plane, the attention mechanism can dynamically discern the temporal distance between interactions. We aim to determine whether this geometric encoding leads to the spontaneous emergence of coherent attention distributions that reflect realistic cognitive phenomena—such as knowledge decay—without relying on handcrafted penalty functions.

> **Research Question 2 (RQ2):**
> *How does the incorporation of continuous time as a geometric property of the latent space influence the model's attention mechanisms, and does it yield interpretable temporal decay patterns distinct from those derived solely from discrete ordinal indices?*

3. METHOD

To address the proposed research questions and isolate the effects of positional encoding from other architectural variables, we utilize the established state-of-the-art models SAINT and SAKT as our baseline frameworks. These models were specifically selected for their benchmark performance in the literature [2] and their reliance on absolute positional embeddings. Unlike models such as AKT or LefoKT [14, 5], SAINT and SAKT do not incorporate explicit temporal decay mechanisms. By replacing their original positional mechanisms with TO-RoPE, we can directly observe the impact of geometric temporal encoding without interference from auxiliary decay components. The following section describes the model architecture.

3.1 Positional Encoding Adjustment

Standard Transformer-based KT models are based on additive absolute positional embeddings [2]. We modify the input formulation to remove these explicit position vectors (P_i), forcing the model to rely solely on the rotation mechanism for sequence information.

SAINT Reformulation. In the original SAINT architecture, the position is added as an absolute learnable vector in the response and exercise embeddings. We simplify the input representation for the encoder ($\mathbf{E}$) and the decoder ($\mathbf{R}$) as follows:

$$\mathbf{E}_i = \mathbf{kc}_i + \mathbf{q}_i \tag{5}$$

$$\mathbf{R}_i = \mathbf{a}_i \tag{6}$$

Where $\mathbf{kc}_i$, $\mathbf{q}_i$, $\mathbf{a}_i \in R^d$, represent, respectively, the embedding for the Knowledge Component, Question ID, and answer correctness at step i and d the dimension of the latent space. Note that the positional term $\mathbf{P}_i$ is explicitly removed.

SAKT Reformulation. Similarly for SAKT, we remove the positional embedding from the interaction matrix formulation. The activity matrix ($\mathbf{E}$) remains unchanged, while the interaction matrix ($\hat{\mathbf{M}}$) is defined as:

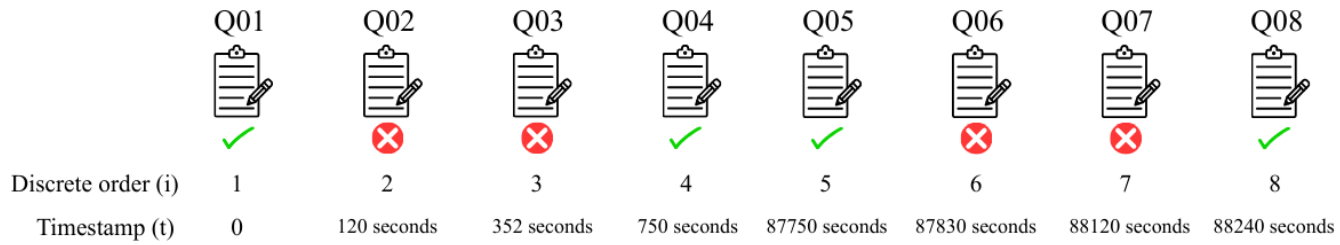

Figure 1: Illustration of the dual-coordinate system used in TO-RoPE. While the discrete order (i) treats interactions as uniformly spaced steps ($i \in \{1, \ldots, 8\}$), the continuous timestamp (t) captures the real-world irregularity of learning sessions, such as the large gap observed between Q04 and Q05 ($\Delta t \approx 24h$). TO-RoPE utilizes both coordinates to rotate the latent representations.

$$\hat{\mathbf{M}} = \begin{bmatrix} \mathbf{M}_{s_1} \\ \mathbf{M}_{s_2} \\ \vdots \\ \mathbf{M}_{s_i} \end{bmatrix}, \tag{7}$$

Where $\mathbf{M}_{s_i} \in R^{2E \times d}$ corresponds to the embedding projection of the student interaction tuple $(\mathbf{q}_i, \mathbf{a}_i)$.

With these modifications to the input embeddings, positional information is no longer additive; instead, it is injected directly into the attention mechanism via geometric rotations. We apply Time-and-Order RoPE (TO-RoPE) to rotate the query ($\mathbf{q}$) and key ($\mathbf{k}$) vectors conditioned on both the discrete sequence index (i) and the continuous real-time timestamp (t):

$$Q_{\text{rot}} = \text{TORoPE}(Q, i, t) \tag{8}$$

$$K_{\text{rot}} = \text{TORoPE}(K, i, t) \tag{9}$$

The attention score is subsequently computed using these rotated projections:

$$\text{Score}(i, j) = \frac{Q_{\text{rot}} K_{\text{rot}}^{\top}}{\sqrt{D_k}}, \tag{10}$$

By defining position as a rotation in the latent space, the inner product naturally encodes the relative distance between interactions in terms of both discrete order (Δi) and continuous elapsed time (Δt). In our implementation, we define the temporal coordinate t as the absolute cumulative time (in seconds) relative to the student's first interaction ($t_0 = 0$). Thus, while the model receives absolute timestamps as input, the rotation mechanism ensures that attention scores represent the relative time intervals between interactions. Figure 1 illustrates the alignment between these discrete order indices and the cumulative timestamps.

3.2 Separation Strategy

To effectively encode both discrete sequential order (i) and continuous elapsed time (t), we adopt the **Split-by-Dimension** strategy proposed by Wei et al. [27]. Wei et al. [27] suggested that integrating both signals into a single rotation plane can lead to destructive interference, in which conflicting phase shifts of time and order cancel each other out, destabilizing the attention mechanism. The Split-by-Dimension approach mitigates this by isolating the signals into orthogonal subspaces.

Formally, we partition the latent dimension d of each attention head into two disjoint sets of rotation planes: P (Order) and T (Time). We introduce a hyperparameter $\lambda \in [0, 1]$ to control the time capacity ratio. It defines the proportion of dimensions allocated to temporal encoding.

Let $\Psi_k \in \{0, 1\}$ be a gate function for the k-th rotation plane, determined by λ:

$$\Psi_k = \begin{cases} 1 & \text{if } k < (1-\lambda) \cdot \frac{d}{2} \quad \text{(Order Subspace)} \\ 0 & \text{if } k \geq (1-\lambda) \cdot \frac{d}{2} \quad \text{(Time Subspace)} \end{cases} \tag{11}$$

The rotation angle θ_k for a given interaction state (i, t_i) is then defined as:

$$\theta_k = \Psi_k \cdot (i \cdot \omega_k^p) + (1 - \Psi_k) \cdot (t_i \cdot \omega_k^t) \tag{12}$$

Here ω_k^p and ω_k^t are the angular frequencies derived from the geometric progression for order and time, respectively. $\lambda = 0.0$ implies a standard positional encoding (pure order), while $\lambda = 1.0$ results in a model driven purely by continuous time intervals. This mechanism allows the model to explicitly balance the inductive bias between sequence and time. Figure 2 illustrates this allocation.

3.3 Frequency Adjustment

To enable the model to capture both short-term immediate dependencies and long-term retention patterns, the angular frequencies of the rotation embeddings must be carefully calibrated. Following the methodology proposed by Wei et al. [27], we adopt a logarithmic frequency scale to ensure adequate resolution across different temporal scales.

The angular frequency ω_k for the k-th rotation plane within a specific subspace is defined as:

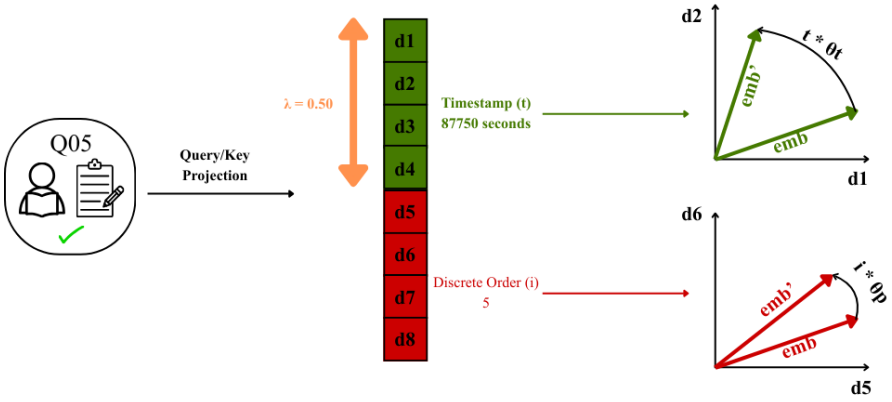

Figure 2: Illustration of the Split-by-Dimension strategy applied to the interaction $Q05$ with a capacity ratio $\lambda = 0.50$. The latent vector is partitioned into Time ($d1 - d4$) and Order ($d5 - d8$) subspaces. The diagram on the right shows how the first pair of dimensions in the time subspace ($d1, d2$) rotates under the timestamp ($t = 87550$), while the corresponding pair in the order subspace ($d5, d6$) rotates with the discrete index ($i = 5$). Note that this rotation process is repeated for all subsequent 2D sub-planes within each subspace (e.g., $d3, d4$ and $d7, d8$) using their respective frequencies from the geometric progression.

Table 1: Summary of the datasets used in our experiments, detailing the number of students with sequence lengths exceeding the extrapolation windows.

Dataset	Year(s)	Interactions	Students	Questions	KCs	Student Count with length $> L$				
						100	200	300	400	500
Proprietary	2023–2025	6,628,695	38,094	2,413	1,435	22,828	11,884	7,472	3,261	1,647
EdNet	2017–2019	95,293,926	784,309	13,169	188	112,558	76,718	59,108	48,087	40,260
ASSIST2017	2004–2006	942,816	1,709	3,162	102	1,647	1,390	1,139	930	750

$$\omega_k = \omega_{max} \left(\frac{\omega_{min}}{\omega_{max}} \right)^{\frac{k-1}{N-1}} \tag{13}$$

Where N represents the number of rotation planes (2D subspaces) allocated to the specific feature (time or order) and $k \in \{1, \ldots, N\}$ is the index of the plane. The boundary frequencies, ω_{max} and ω_{min}, are derived from the target wavelengths (periods) β. Where β_{min} and β_{max} represent the lower and upper bounds of the resolution (wavelengths), respectively.

$$\omega_{\max} = \frac{2\pi}{\beta_{\min}}, \qquad \omega_{\min} = \frac{2\pi}{\beta_{\max}} \tag{14}$$

4. EXPERIMENTS

4.1 Datasets

Previous works, such as Torralba and Efros [24] and Ben-David et al. [6], demonstrate that the intrinsic characteristics of each dataset, such as data distribution and collection biases, can significantly affect model performance. To mitigate performance gains arising from domain-specific overfitting, we selected three datasets with distinct characteristics for our evaluation.

The first is a **Proprietary Dataset**, a medium-sized corpus collected between 2023 and 2025 from response logs of students enrolled in various engineering courses within a Brazilian higher education institution. The second dataset is **EdNet** [10], a large-scale public benchmark containing interactions from Korean students collected between 2017 and 2019 for the TOEIC (Test of English for International Communication) exam. Finally, the third dataset is **ASSISTments 2017** [4], a small dataset collected between 2004 and 2006 that comprises data from middle school students interacting with an Intelligent Tutoring System (ITS).

The combined use of these datasets allows us to evaluate model behavior across diverse scenarios, ranging from controlled educational environments to large-scale, real-world contexts. Table 1 summarizes the descriptive statistics for each dataset.

4.2 Data Partitioning and data processing

Yadav and Shukla [29] demonstrate that k-fold cross-validation typically offers the most robust evaluation metric. However, the authors also highlight the need to balance performance generalization with computational cost, which scales linearly with k. Given the massive scale of the EdNet dataset and the requirement to perform grid searches for the TO-RoPE parameter λ, strictly adhering to k-fold cross-validation would render the experimental timeline infeasible. For instance, training a single variation of the SAINT architecture on EdNet requires approximately 13 hours on an NVIDIA A100 GPU.

Due to these computational constraints, we adopted a student-level holdout strategy for the proprietary and EdNet datasets, using an 80/10/10 split (Train / Validation / Test). The

partitioning was based on unique student identifiers, ensuring that students in the training set did not appear in the validation or test sets.

Regarding data processing, we addressed three critical scenarios:

- **Sequence Splitting:** To fully utilize extensive interaction histories, students with sequence lengths $L > L_{window}$ were partitioned into $N = L/L_{window}$ non-overlapping sub-sequences. This ensures that the model learns from the entire student's trajectory, rather than just the initial interactions.
- **Cold Start:** Following the findings of Bhattacharjee and Wayllace [7], students with fewer than 5 interactions were removed from the datasets, as models lack sufficient context to make reliable predictions for such sparse histories.
- **Padding:** For sequences (or sub-sequences) with lengths $L < L_{window}$, we appended padding tokens. These tokens are masked during training to prevent them from influencing the loss calculation.

In contrast, for the **ASSISTments 2017** dataset, due to its smaller sample size, we adopted a nested evaluation strategy to ensure statistical robustness. First, we randomly selected 20% of the students as a test set. The remaining 80% of the data was used for **5-fold cross-validation** to train the model and tune hyperparameters. This separation ensures that the final performance metrics are evaluated on a pristine set of unseen students.

4.3 RQ1: Length Extrapolation Analysis

To answer RQ1, we evaluated the capability of TO-RoPE to generalize to sequence lengths significantly longer than those observed during training by adopting a *train-short, test-long* protocol. The training and validation sets were divided into fixed windows of 100 interactions per student, following the configuration utilized by Choi et al. [9]. Interactions were classified chronologically by timestamp. During the testing phase, extrapolation capability was evaluated on windows of increasing lengths: 100, 200, 300, 400, and 500 interactions.

It is crucial to emphasize that the choice of a restricted training window ($L = 100$) serves a dual purpose: it aligns with previous baselines and, more importantly, acts as a rigorous **stress test** for length generalization. Training on longer sequences (e.g., 500) and testing on similar lengths would fundamentally assess the model's *interpolation* capabilities. By strictly limiting training to short sequences and evaluating on extended horizons, we effectively isolate and quantify the model's capacity for real *length extrapolation* based on the learned geometric properties of the latent space.

Based on previous work [2, 20, 8], the Area Under the ROC Curve (AUC) was used as the primary performance metric. To ensure robustness, each model was executed with 5 different random seeds, and the results are reported as mean and standard deviation ($\mu \pm \sigma$). Due to a limited sample size ($N = 5$) imposed by computational constraints, statistical significance was assessed using the Wilcoxon signed-rank test. We compared the baseline models (SAKT, SAINT) against their TO-RoPE variants. This non-parametric test was selected because it does not assume normality and is suitable for comparing classifiers across multiple runs [12]. Since our research hypothesis investigates the superiority of TO-RoPE over baselines, a one-sided test was adopted.

Additionally, to quantify stability, we report the slope coefficient (α) from a linear regression of AUC values across different test window sizes. This metric indicates the trend of performance gain or degradation as the sequence length increases. For readability, the reported coefficients were scaled by a factor of 10000.

4.4 Analysis of Attention Dynamics

To assess RQ2, we investigated how the model interprets the temporal dimension, and to validate whether TO-RoPE effectively encodes continuous time as a geometric property, we conducted an empirical analysis of the attention weights. Our objective was to determine whether the incorporation of time ($\lambda > 0$) induces distinguishable attention patterns compared to purely ordinal baselines ($\lambda = 0$), specifically in terms of the modeling of knowledge decay.

We extracted the attention matrices $A \in \mathbb{R}^{L \times L}$ from the inferences of the test set. To identify global patterns, we computed the mean attention scores averaged across all heads and layers for distinct configurations of λ. These scores were then aggregated based on the time distance (Δt) between interactions i and j. This aggregation strategy allows us to observe attention decay across varying temporal scales—ranging from immediate responses (seconds) to long-term retention intervals (weeks or months)—and to verify whether the model spontaneously learns to penalize older information based on elapsed time.

4.5 Hyperparameter Configuration

To ensure fair comparisons and reproducibility, hyperparameter tuning was tailored to each dataset's scale. For large-scale datasets (*EdNet* and *Proprietary*), we adopted established configurations from the literature to manage computational costs. In contrast, for the smaller dataset *ASSISTments2017*, we performed a grid search to identify optimal settings.

Across all model architectures, batch sizes were determined by dataset scale to optimize throughput on the NVIDIA A100 GPU: we employed a batch size of **512** for the massive *EdNet* and **128** for both the *Proprietary* and *ASSISTments2017* datasets.

For the **SAINT** architecture (and its TO-RoPE variants), we utilized the configuration proposed by Choi et al. [9] for EdNet and Proprietary datasets: latent dimension $d = 512$, $h = 8$ attention heads, $L = 4$ layers, and dropout $p = 0.1$. For *ASSISTments2017*, we searched over $d \in \{64, 256, 512\}$, $h \in \{4, 8\}$, $L \in \{1, 2, 4\}$, and $p \in \{0.05, 0.10, 0.20\}$.

For **SAKT**, we followed the recommendations of Pandey et al. [19] for large datasets, setting $d = 200$ and $p = 0.10$. For *ASSISTments2017*, we tuned the latent dimension over $d \in \{50, 100, 200\}$.

For the AKT and LefoKT-AKT-NF baselines (with ALiBi), we strictly adhered to the hyperparameter settings de-

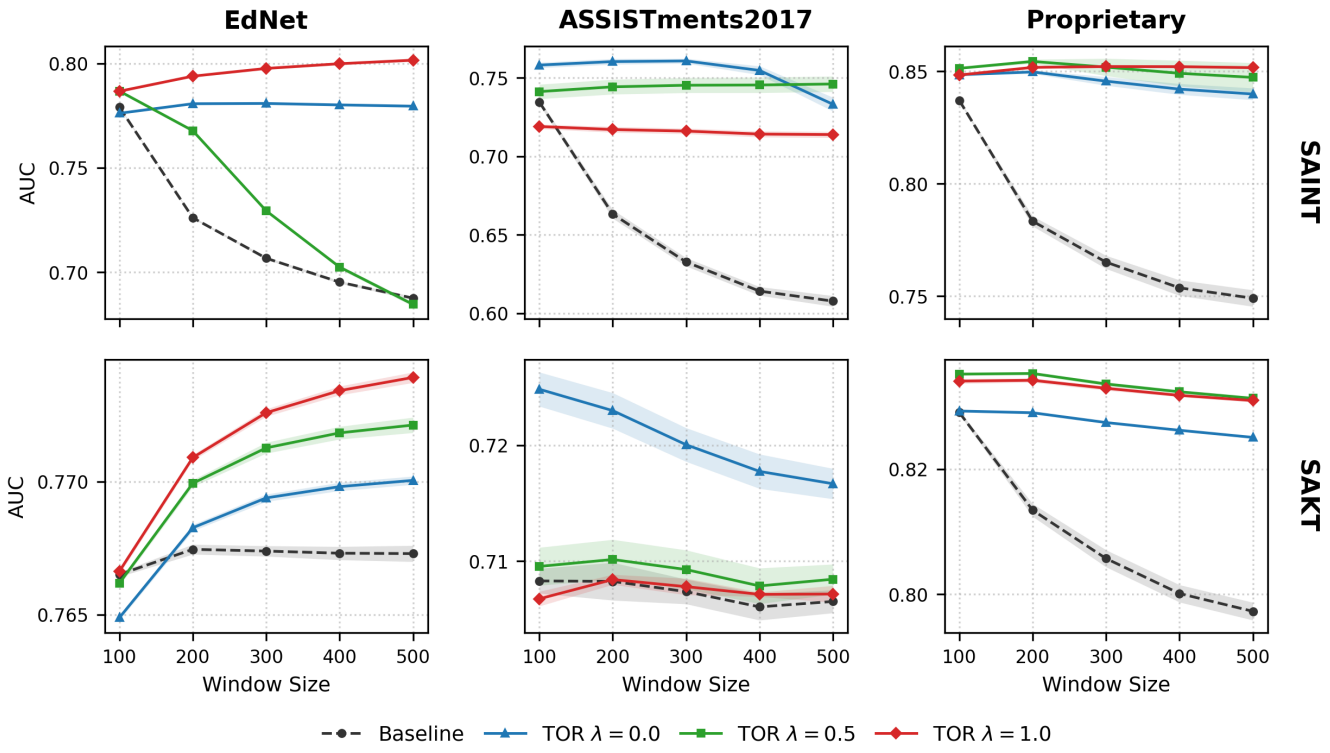

Figure 3: Average AUC per extrapolation window size over 5 independent runs

scribed in their respective original papers [14, 5] for large-scale datasets: $h = 8$ heads, latent dimension $d = 512$, and dropout $p = 0.10$. However, for *ASSISTments2017*, we performed a specific grid search over the latent dimension $d \in \{64, 256, 512\}$, number of heads $h \in \{4, 8\}$, and dropout rates $p \in \{0.05, 0.10, 0.20\}$.

All models were optimized using the Adam optimizer. We searched for the learning rate $l_r \in \{1e^{-5}, 5e^{-5}, 1e^{-4}, 5e^{-4}, 1e^{-3}\}$, finding that $l_r = 1e^{-4}$ is optimal for the majority configurations. Weights were initialized using the Xavier initialization scheme [15].

To avoid overfitting, we employed an *early stopping* mechanism with patience of 10 epochs, monitoring the AUC metric on the validation set with a minimum improvement delta of 10^{-4}. The maximum training duration was set at 50 epochs for SAINT-based models and 100 epochs for SAKT, AKT, and LefoKT.

Finally, for the **Time Subspace**, we set $\beta_{min} = 1$ second across all datasets to capture fine-grained interactions. The upper bound β_{max} is set to the nearest power of 10 exceeding the maximum timestamp observed in each dataset, ensuring that the rotation mechanism covers the entire temporal span without aliasing. Table 2 details these dataset-specific bounds.

For the **Order Subspace**, we fix $\beta_{min} = 1$ and $\beta_{max} = 500$. The latter corresponds to the maximum sequence length evaluated during our length extrapolation experiments, ensuring distinct positional signatures throughout the extended window.

Table 2: Frequency resolution bounds (β_{max}) for the temporal subspace across datasets.

Dataset	Max Time Observed (s)	$\beta_{\max}$ (s)
Proprietary	$\approx 7.80 \times 10^7$	10^8
EdNet	$\approx 8.17 \times 10^7$	10^8
ASSIST2017	$\approx 5.02 \times 10^7$	10^8

5. RESULTS

5.1 RQ1: Length Extrapolation

The initial results present the length extrapolation capabilities of the TO-RoPE models compared to baselines, with performance trajectories visualized in Figure 3 and quantitative metrics detailed in Table 3.

In the **EdNet** dataset, the SAINT + TO-RoPE configuration ($\lambda = 1.00$) achieved the highest AUC values across all test windows, distinguishing itself by a growing performance trend as the sequence extended ($10000 \cdot \alpha = +0.35792$). In contrast, both the SAINT baseline and the variation with $\lambda = 0.50$ exhibited a performance collapse, with sharp AUC drops starting from the first extrapolation window. Regarding SAKT, the time-focused variation ($\lambda = 1.00$) led across all window lengths; however, the gains were significantly less expressive than those observed in SAINT. Variations with $\lambda = 0.50$ and $\lambda = 0.00$ demonstrated intermediate performance, while the baseline remained stable but with AUC scores inferior to all rotation-based variations from 200 in-

teractions onward. Models such as AKT and LefoKT maintained positive slopes and outperformed SAKT variants, but did not reach the performance level of SAINT + TO-RoPE ($\lambda = 1.00$).

For **ASSISTments2017**, the SAINT + TO-RoPE variation with $\lambda = 0.00$ (purely order-based) presented the best performance in windows from 100 to 400 interactions. At the limit of 500 interactions, the LefoKT-AKT-NF + ALiBi model obtained the superior result. Contrary to trends in EdNet, the temporal variation ($\lambda = 1.00$) in SAINT underperformed, yielding consistently lower results than the order-based variants. The SAINT baseline showed an acute performance decline in the extended windows. In the SAKT model, the variation $\lambda = 0.00$ was the most effective, leading both in absolute AUC values and stability metrics, whereas temporal variation led to performance degradation. The AKT outperformed all SAKT variants in this dataset, though it remained inferior to SAINT.

Results on the **Proprietary** dataset exhibited mixed behavior. The SAINT + TO-RoPE configuration with $\lambda = 0.50$ led in the initial windows of 100 and 200 interactions, while the purely time-based version ($\lambda = 1.00$) obtained the best results in the 300, 400, and 500 windows, also registering the highest stability (α) among SAINT-based models. In the case of SAKT, the hybrid model ($\lambda = 0.50$) was superior to the other variations in all the extensions tested. The baselines for both models (SAINT and SAKT) suffered significant performance drops. Finally, the AKT and LefoKT-AKT-NF + ALiBi models demonstrated competitiveness, maintaining positive stability slopes, with LefoKT reaching the highest overall stability recorded for this dataset ($10000 \cdot \alpha = +0.10907$).

Additionally, we computed the average ordinal distance ($\overline{\Delta O}$) within each bucket to understand the density of sessions. These statistics are summarized in Table 4.

5.2 RQ2: Temporal Attention Dynamics

Figure 4 illustrates the attention decay patterns as a function of the temporal distance between interactions. A prominent feature is observed in the EdNet dataset with the SAINT architecture. The temporal model ($\lambda = 1.00$) concentrates significantly higher attention weights on short-term interactions ($1s \leq \Delta t \leq 1h$) compared to the ordinal baseline. As the time interval extends beyond 1 hour, both curves con-

Table 4: Temporal distribution and average ordinal distance per time bucket across datasets.

Dataset	First int.	Hour		Day		Week		Month		> 1 Month	
	%	%	$\overline{\Delta O}$	%	$\overline{\Delta O}$	%	$\overline{\Delta O}$	%	$\overline{\Delta O}$	%	$\overline{\Delta O}$

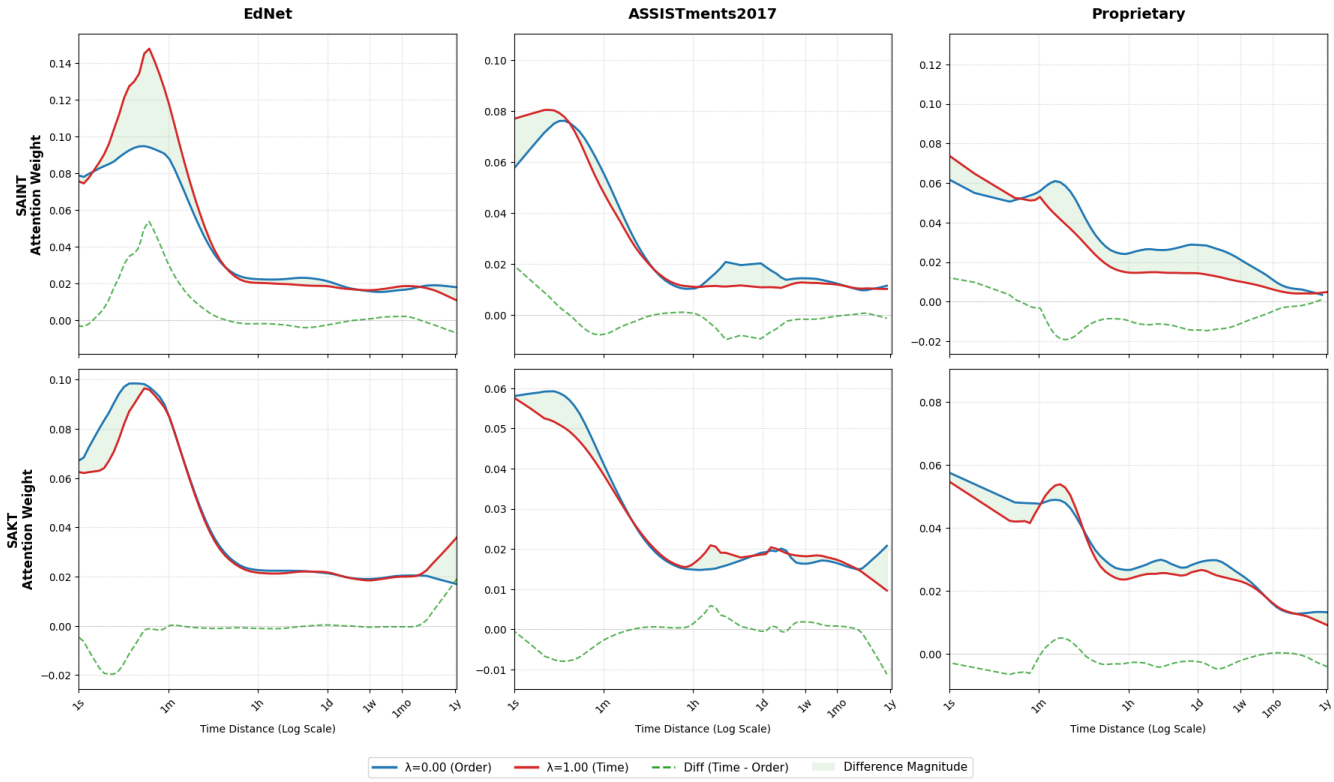

Figure 4: Average attention score per logarithmic time distance between interactions

verge to similar low-magnitude values. On the other hand, for the SAKT architecture on EdNet, a divergent pattern emerges: the ordinal model ($\lambda = 0.00$) assigns higher attention to immediate interactions ($1s \leq \Delta t \leq 1min$) than the temporal variant. For longer intervals ($1mo \leq \Delta t \leq 1y$), the difference between the two configurations stabilizes near zero.

Regarding ASSISTments2017, while there are differences between the ordinal and temporal attention distributions for both SAINT and SAKT in the short-to medium term, the magnitude of these deviations is less pronounced than those observed in the EdNet/SAINT scenario.

Finally, in the Proprietary dataset, the SAINT model with temporal encoding ($\lambda = 1.00$) exhibits a dual behavior: it assigns higher weights to very short-term interactions while systematically suppressing attention to distant past interactions more aggressively than the ordinal model. A similar trend is observed in SAKT, except that in the short term, the ordinal model predominates.

Despite these architecture-specific variations, a consistent global pattern is evident across all models and datasets: attention scores exhibit a natural decay as the temporal interval increases. This decay is notably sharper for EdNet and ASSISTments2017, whereas the Proprietary dataset displays a smoother, more gradual decline.

In an order-based model, such as SAINT + TO-RoPe ($\lambda = 0.00$), an item 20 steps ago is treated as a distant context. However, TO-RoPE ($\lambda = 1.00$) correctly identifies that these 20 items occurred on the same day, indicating a learning burst. This explains the attention patterns observed in Figure 5:

- **Order-based ($\lambda = 0.00$):** Attention is strictly diagonal, suffering from recency bias.
- **Time-based ($\lambda > 0$):** The attention mechanism diffuses off the diagonal, successfully attending to temporally clustered interactions that are ordinally distant.

This ability to compress bursts (treating them as simulta-

neous) while respecting long-term gaps allows the model to better capture complex temporal patterns, driving the superior extrapolation results seen in EdNet.

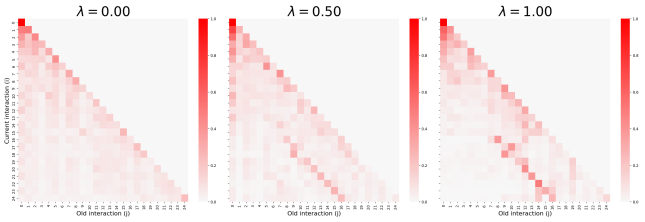

Figure 5: Average attention scores (per head) for distinct λ configurations on the EdNet dataset. Higher λ values allow the model to attend to ordinally distant but temporally close interactions (bursts).

The interplay between time and order is most nuanced in the Proprietary dataset, where the hybrid configuration ($\lambda = 0.50$) often yields superior stability. Unlike the self-paced nature of EdNet, higher education engineering courses follow a structured curriculum where sequential prerequisites are strictly enforced (favoring Order). However, students frequently engage in "cramming" sessions before exams, generating high-frequency bursts (favoring Time). A balanced λ allows the model to simultaneously respect the curricular sequence while geometrically compressing these intensive study sessions. This suggests that TO-RoPE is not a one-size-fits-all solution, but a flexible framework adaptable to the specific pedagogical design of the learning environment.

6. DISCUSSION

The inclusion of TO-RoPE significantly enhances length extrapolation capabilities, but the magnitude of these gains is highly sensitive to the dataset's characteristics. To deconstruct these performance variations, we analyzed the temporal distribution of the interactions. We aggregated interactions into time buckets based on the elapsed time since the student last engaged with the same KC.

Beyond specific dataset characteristics, the fundamental success of TO-RoPE in length extrapolation (RQ1) stems from the geometric property of translation invariance. Standard models fail because the absolute embeddings (P_i) learned for positions $i \in [0, L_{train}]$ are undefined or semantically meaningless for $i > L_{train}$. In contrast, TO-RoPE encodes the relative distance between interactions. For the attention mechanism, a temporal gap of $\Delta t = 1$ hours possesses the same geometric representation, whether it occurs at the beginning of a course or after thousands of interactions. This ensures that predictive stability is maintained indefinitely, effectively decoupling the model's context capacity from the fixed window sizes used during training.

The poor performance of the time-only variant ($\lambda = 1.00$) in ASSISTments2017 can be attributed to a low temporal signal-to-noise ratio. As shown in Table 4, nearly 90% of all interactions in this dataset occur within the first hour of contact with a KC. In such a highly dense short-term environment, the continuous timestamp provides negligible additional information beyond the discrete sequence order. Consequently, dedicating latent dimensions to time rotation ($\lambda > 0$) likely displaces valuable ordinal capacity without providing a discriminative signal, effectively acting as noise that degrades performance.

In contrast, EdNet exhibits a heavy-tailed distribution with a significant interaction volume spread across Days (14.25%), Weeks (21.37%), and even Months (7.92%). The table reveals a discrepancy between ordinal and temporal proximity: interactions within the same "Day" or "Week" bucket often have large ordinal distances ($\overline{\Delta O} \approx 49$ and 106, respectively).

Based on the findings regarding RQ2, incorporating continuous time as a geometric property alters the model's attention dynamics by decoupling ordinal distance from temporal distance. The empirical analysis, particularly on the EdNet dataset, reveals that purely order-based models exhibit a strict diagonal focus driven by recency bias—treating a prerequisite 20 steps ago as a distant context regardless of how quickly those interactions occurred. In contrast, the TO-ROPE mechanism effectively compresses rapid-fire bursts of activity. By geometrically recognizing that high-frequency sequences occur within a negligible time window despite their ordinal length, the model spontaneously diffuses attention across these clusters. This confirms that geometric encoding enables the attention mechanism to filter out noise from high-volume interaction bursts and to perceive the cognitive density of a learning session, rather than simply counting steps.

Furthermore, the study demonstrates that interpretable knowledge decay patterns emerge naturally from these geometric rotations, without the need for the handcrafted, monotonic penalty functions used in prior architectures such as AKT or LefoKT. While the attention weights exhibit a spontaneous forgetting curve as the temporal gap increases, the rotation mechanism preserves the norm of the latent vectors rather than imposing bias. This structural property enables the model to attenuate outdated information while still retaining the capacity to revisit and address distant but semantically critical prerequisites when vector alignment is strong. This finding suggests that geometric encoding offers a superior inductive bias, balancing the natural tendency to forget with the ability to recall long-term dependencies when the specific learning context demands it.

This research advances KT research by establishing that student learning trajectories are better modeled as continuous geometric paths in a latent space than as rigid, discrete sequences. The study shows that critical cognitive phenomena, such as memory decay and the spacing effect, can emerge from the relative rotation of the query and key vectors without the need for handcrafted penalty functions or additive biases. This shift challenges the prevailing reliance on absolute positional embeddings by proposing a unified framework that treats discrete order and continuous time as orthogonal yet complementary geometric dimensions.

The practical implications of this study extend to both the computational scalability of lifelong learning systems and the quality of personalized educational interventions. From a systems perspective, the findings demonstrate that models can be trained on efficient, truncated interaction windows (e.g., 100 steps) while maintaining predictive stability over substantially longer student histories (up to 500 steps). This decoupling of training context from inference capac-

ity prevents the performance collapse typical of standard Transformer architectures, allowing platforms to deploy robust models without incurring prohibitive computational costs. Consequently, this framework enables more stable performance predictions for learners with extensive interaction histories, which is essential for reliably tracking student progress across an entire course or even years of study. Furthermore, by accurately capturing natural memory decay, TO-RoPE empowers adaptive systems to deliver smarter, timely interventions, such as scheduling targeted reviews or spaced repetitions based on a student's probability to forget a concept.

7. LIMITATIONS AND FUTURE WORKS

Despite not changing the time complexity of the main attention mechanism, incorporating TO-RoPE adds a computational overhead when searching for the optimal time-capacity ratio hyperparameter (λ). Additionally, the model's effectiveness depends on the dataset's temporal signal-to-noise ratio. In environments with low temporal variance, such as ASSISTments2017, allocating dimensions to time can degrade performance by displacing valuable ordinal information. To address these challenges, future research could use interpretability techniques, such as Attention Rollout, to analyze how individual heads specialize in capturing either short-term bursts or long-term decay.

In terms of baselines, we also recommend expanding the comparative analysis to other time-aware models, such as DKT-Forget [18], Deep Graph Memory Network (DGMN) [1], Long Sequence Temporal Knowledge Tracing (LSTKT) [13], and HawkesKT [26], to evaluate how well TO-RoPE performs compared to these distinct approaches. Furthermore, this framework could be expanded to diverse educational domains, such as Law and Humanities, to investigate how different knowledge structures interact with geometric temporal properties.

ABSTRACT

Understanding what behavioral patterns distinguish successful from unsuccessful problem solving could inform the design of more responsive learning environments. We investigated whether keystroke dynamics during typed mathematics responses reflect differences between correct and incorrect problem solving. Because problem format may influence student engagement and solution strategies, we also examined whether these keystroke patterns vary when problems include images versus text alone. Analyzing 21,938 responses from 570 students, we found that correct responses were characterized by slower, more variable typing with greater use of revision, while incorrect responses often showed patterns suggesting minimal engagement. Responses completed in under five seconds were almost never correct, suggesting a threshold below which meaningful problem solving appears not to occur. Machine learning models achieved modest but stable performance in distinguishing correct from incorrect responses based solely on typing patterns. Counterfactual analysis indicated that these models learned theoretically sensible relationships: the behavioral changes most frequently associated with shifting predictions from incorrect to correct aligned with increased deliberation and engagement. Notably, keystroke patterns remained largely stable across different problem formats, suggesting these behavioral signals may generalize across varied task presentations. These findings contribute to understanding how typing behavior during problem solving relates to correctness.

1. INTRODUCTION

Mathematical problem solving is widely understood as a sequential, multi-stage cognitive process [27, 32]. One of the earliest and most influential articulations of this view dates back to Pólya's four phases—understand the problem, devise a plan, carry out the plan, and look back (evaluating the result) [27]. Each of these stages corresponds to distinct cognitive activities, ranging from initial sense-making to strategic planning, execution, and reflection. Subsequent research has further elaborated these staged models [32, 33, 34], emphasizing that effective problem solving depends not only on domain knowledge but also on strategic control over these phases. Consequently, examining how learners progress through these stages can shed light on why some responses are correct while others are not—for example, errors may arise from early misinterpretation or flawed planning, whereas success may reflect effective planning or careful review.

Because the problem-solving process is latent and multifaceted, researchers have devised various methods to make it observable. Think-aloud protocols have been a popular approach for a few decades: students are asked to verbalize their thoughts while solving problems, providing a running transcript of their reasoning [14]. Such protocols have yielded rich insights into strategies and misconceptions. Schoenfeld [32, 33] used think-aloud data to reveal, for example, that unsuccessful solvers often fail to plan or monitor their progress, whereas expert problem solvers exhibit effective self-regulation in real time. However, think-aloud methods have well-known limitations. They are intrusive—the act of continuously verbalizing can interfere with the natural flow of thinking—and thus may alter the very process under study [30]. Ericsson [13] notes that prompting students to articulate thoughts can slow cognitive processing or cause them to oversimplify decisions. Retrospective interviews (asking students to describe their solution after the task) lack these limitations but rely on memory and can thus be inaccurate [40].

Another window into problem-solving cognition is eye-tracking, which records where and for how long a solver looks at different parts of a problem [25, 24]. Eye movements provide

a fine-grained trace of attention and can indicate which information a student is focusing on or neglecting. For example, eye-tracking studies of algebra and word problems have shown that attention patterns differ between successful and unsuccessful solvers. Hegarty et al. [17] found that students who solved word problems correctly tended to form a coherent mental model of the situation, as evidenced by their gaze: they spent more time inspecting relevant relationships in the text/diagram, whereas poorer solvers often fixated on superficial keywords or numbers in a repetitive way. Similarly, Sušac et al. [36] used eye-tracking to compare novices and experts solving equations; experts had more efficient eye scans (fewer, more focused fixations), suggesting they quickly homed in on important elements, whereas novices' eyes wandered more, indicating uncertainty. Furthermore, Schindler et al. [31] demonstrated that eye-tracking can reveal the temporal sequence of solution steps a student takes—effectively mapping out their step-by-step approach—with greater precision than think-aloud or video analysis. However, eye-tracking too has practical limitations. It requires specialized hardware and controlled settings to achieve full precision [18] and scaling it to thousands of students in real classrooms is costly and logistically complex. Moreover, while less obtrusive than think-aloud [28], the presence of equipment and the laboratory setup may still not reflect a student's natural study environment.

Model tracing offers another method for studying students' problem-solving processes, when conducted using cognitive architectures like ACT-R [2]. The ACT-R architecture models cognition as a sequence of production rules and memory operations, enabling fine-grained simulations of reasoning. Koedinger and MacLaren [19] developed the Early Algebra Problem Solver (EAPS), which uses ACT-R to account for both informal and formal strategies students use when solving algebra problems and to predict common patterns of error based on cognitive processes. In model-tracing, each step of a student's process is evaluated against an expert-authored model for alignment to both correct and incorrect (buggy) reasoning [2]. However, this approach requires interfaces that explicitly reify each step of problem solving—meaning that students must type out or select every intermediate action [2]. Because this design can slow down the problem-solving experience and restrict the flexibility of students' strategies, many intelligent tutoring systems opt not to use this level of fine-grained model tracing [1].

In today's computer-based learning platforms, every student interaction can be logged [26, 11, 37]. This can (but often does not) include keystroke data—the sequence of keys pressed, along with timing information—when students type out responses. Such keystroke dynamics are an increasingly attractive source of cognitive process data in education because they are captured naturally, at scale, with minimal intrusion [15, 37]. Whenever students type an answer, how they type (pauses, deletions, revisions, etc.) is being recorded behind the scenes, without requiring the student to do anything extra. This yields a high-resolution trace of the writing or problem-solving process, time-stamped to the millisecond. In contrast to one-on-one think-aloud sessions or lab eye-tracking, keystroke logging is cheap and massively scalable—it can unobtrusively collect data from an entire online class or platform with hundreds of thousands of submissions [39]. It is also ecologically valid: students solve problems in the interface as they normally would (typing their response), so the data reflect authentic behavior in situ rather than under experimental observation [21].

Research in writing and programming has demonstrated the promise of keystroke analytics for inferring cognitive processes. For example, in essay writing tasks, keystroke logs have been used to measure pausing patterns, revision frequency, and text production bursts, which correlate with writing quality and strategy use [3, 38]. Several studies have linked certain keystroke features to performance outcomes. The number of revisions (edits and deletions) and the timing of those revisions have been tied to better performance in some contexts—e.g. writers who pause to revise frequently often produce more coherent texts [35, 42]. Keystroke-derived features such as interval timings (pauses between keystrokes or between sentences) can reflect the writer's cognitive effort or the points of difficulty [16]. Overall, prior work suggests that keystroke patterns carry informative signals about underlying cognitive processes [15].

Despite substantial prior work, gaps still remain in establishing how keystroke dynamics map to students' problem-solving processes. Keystroke data are inherently low-level behavioral traces, and their cognitive interpretation is often ambiguous: a prolonged pause may reflect difficulty, strategic planning, or disengagement, while rapid keystroke bursts may indicate fluent execution or unproductive guessing. Prior research has attempted to disambiguate meaning by extracting extensive sets of keystroke features and examining their associations with performance and other indicators [16]. However, findings across studies show limited convergence, in part because of substantial variability in the features selected for analysis [21, 35, 11]. Moreover, Conijn et al. [11] show that relationships between keystroke features and performance outcomes are context-dependent. As a result, further empirical work is needed to examine whether keystroke dynamics reliably differentiate between processes and even between correct and incorrect problem-solving outcomes.

Conijn et al. [11] note that these relationships can differ between tasks, yet there has been insufficient examination of how the problem context or format influences keystroke patterns. Other keystroke-based studies in education have looked at relatively uniform task types within-study (e.g. essay writing, short-answer responses in text form). However, in a domain like math, tasks can vary widely. For instance, an "open-ended" response might be prompted by pure text or accompanied by a diagram or image. In such cases, the presence of a diagram or image could plausibly alter students' engagement and problem-solving behaviour. Koedinger and Nathan [20] show that the format of a problem may shape students' solution approaches and performance. Furthermore, Chu et al. [9] demonstrate that student strategy is impacted by the presence of diagrams. However, to our knowledge, no prior work has systematically compared keystroke dynamics between math problems with diagrams or images and those presented in text-only format.

Finally, while prior studies have generally focused on correlating specific keystroke features with performance, they

rarely address the question of what changes in a student's keystroke behavior might be associated with a higher chance of success. Identifying minimal plausible shifts in behavior—a standard step in contemporary explainable artificial intelligence research [23]—could be very valuable.

This study thus aims to advance our understanding of fine-grained keystroke dynamics in mathematical problem solving along three dimensions: association with correctness, influence of problem format, and actionable differences between success and failure. We analyze an extensive dataset of 21,938 open-ended responses collected from a widely-used online math learning platform. Each response is accompanied by detailed keystroke logs capturing the student's typing and editing process. Our investigation centers on engineered features that quantify temporal aspects, revision behaviors, and the entropy or unpredictability of the keystroke sequence. We first examine the statistical associations between these keystroke features and answer correctness. Second, we explicitly compare image-based versus text-only questions. Third, we perform a counterfactual analysis using explainable artificial intelligence techniques to identify minimal behavioral changes associated with shifting an outcome from incorrect to correct. Aggregating such analyses over thousands of cases, we highlight which minimal changes would most frequently turn failure into success (according to the underlying machine-learned models being studied).

2. METHODS

2.1 Data

2.1.1 Source and Context

This study utilized de-identified data from an online mathematics learning platform that uses diagnostic assessment and adaptive learning pathways. The platform provides diagnostic quizzes, instructional videos, and practice activities intended to help students resolve misconceptions and improve their understanding. The learning sequence for a topic on the platform begins with five multiple-choice diagnostic questions. If a student answers a question incorrectly twice in a row, they enter a Learn phase to review worked examples and videos. Following this, the student proceeds to the Practice phase, which consists of a set of worksheet questions. Our study focuses exclusively on this Practice phase, as students provide open-ended, typed answers. These responses generate detailed keystroke logs. All personally identifiable information (PII) was removed prior to data access. The final dataset was constructed by merging several source files, including the raw keystroke logs, the students' final answers, and the worksheet question metadata. This merging process resulted in a final dataset of 21,938 unique student–question transactions from 570 students, which was used for all subsequent analyses.

2.1.2 Correctness Labelling

The worksheet data did not include pre-existing correctness labels. The dataset provided each student's final submitted response alongside an expert-authored reference answer. To label the data at scale, we developed an automated labeler using GPT-4o. The model was prompted, via a few-shot approach, to act as a mathematical evaluator, comparing each student's response to the expert-authored reference. The prompt instructed the model to determine if the two answers were mathematically equivalent, providing explicit rules to accept common variations. These rules included, for example, handling commutative expressions (e.g., $3x+2$ vs. $2+3x$), numerical approximations, differences in formatting (e.g., £1,057.50 vs. 1057.50), and the presence or absence of units. To validate this labeler, we first established a ground truth by having two human coders independently annotate a 200-response random sample, with high inter-rater reliability ($\kappa = 0.95$). In the small number of cases where the humans disagreed, social moderation was used to determine a final consensus label. The GPT-4o labeler, when tested against these human labels, demonstrated excellent performance, also achieving a Cohen's κ of 0.95, as well as a precision of 0.97 and a recall of 0.95. Following this successful validation, the GPT-4o labeler was used to provide correctness labels for the full dataset of 21,938 responses.

Table 1: Engineered keystroke and contextual features used in the analysis.

Feature	Definition
Keystroke Edit Distance	Levenshtein distance between the full raw keystroke sequence and the final submitted answer.
Seconds per Keystroke	Total time spent on the response divided by total number of keystrokes.
Keystroke Entropy	Shannon entropy of the keystroke sequence.
Correction Density	Number of correction keys (Backspace, Delete) divided by log-transformed total time.
Correction Proportion	Number of correction keys divided by total keystrokes.
Keystroke Efficiency Ratio	Final answer length divided by total keystrokes.
Average Seconds Between Keys	Mean inter-keystroke time (seconds) for a question attempt.
Variation in Seconds Between Keys	Standard deviation of inter-keystroke times (seconds) for a question attempt.
Fast Response	Indicator variable equal to 1 if total response time $\leq$ 5 seconds.
Slow Response	Indicator variable equal to 1 if total response time $>$ 300 seconds (5 minutes).
Pasted	Indicator variable equal to 1 if total keystrokes exceed total seconds taken.
Worksheet Question Has Image	Indicator variable equal to 1 if the question has an image attached.

2.1.3 Keystroke Data and Feature Engineering

For each student response to a worksheet question, a detailed keystroke log was produced. These logs contained the sequence of key presses along with associated metadata, capturing information on timing, editing behaviors, and other aspects of the input. An illustrative example of the data captured for a single student–question response is shown in Table 2. From these raw data, we engineered a set of

Table 2: Selected columns of a row in the raw data. HasImg = WorksheetQuestionHasImage, ⟨BS⟩ = Backspace, ←= Left Arrow

Question	HasImg	Reference Answer	Final Input	Time(sec)	Input Keystroke
Calculate 2548 − 362	False	2186	2186	167	← 218y ⟨BS⟩ 6

features to quantify the temporal (timing-related), corrective (editing-related), and compositional (content-related) aspects of the student's typing activity. These were analyzed alongside contextual data for each problem, including a feature indicating whether the question contained an image (see Figure 1 for an example). A summary of all engineered features, including their definitions is provided in Table 1. The distribution of the target label (correctness) across the final dataset was 72% incorrect and 28% correct, while the contextual image feature was nearly balanced, with 49% of transactions pertaining to questions with images and 51% to those without.

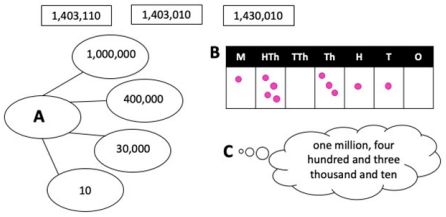

Figure 1: Example of an image-based worksheet question (QID 219: "Match each representation to its corresponding number in figures").

2.2 Analysis

As stated in Section 1, the goal of this study is to examine how fine-grained keystroke dynamics—such as typing latency, editing behaviors, and input variability—relate to answer correctness, and to identify how these process-level patterns, modulated by problem format (e.g., image vs. text), differentiate correct from incorrect problem-solving.

2.2.1 *Exploratory Analysis*

To investigate the relationships between student keystroke patterns, problem format, and answer correctness, we conducted a series of statistical analyses. First, to determine whether individual features were associated with the outcome, we tested each feature against the binary correctness label. We used the Mann–Whitney U test for continuous features (e.g., *variation in seconds between keys*) and Fisher's Exact Test for binary categorical features (e.g., *Worksheet Question Has Image*, *Pasted*), as appropriate for each data type. Second, we conducted a separate comparison to examine whether problem format itself influenced keystroke behavior. Specifically, we used the Mann–Whitney U test to compare continuous keystroke feature distributions based on problem format alone (image vs. text-only), to determine whether the presence of an image, in isolation, was associated with different keystroke patterns.

For all statistical tests, p-values from multiple comparisons were corrected using the Benjamini–Hochberg false discovery rate (FDR) procedure. For the Mann–Whitney U tests, effect sizes were computed using Cliff's Delta, which provides a non-parametric measure of group superiority. For the Fisher's Exact tests, we computed the odds ratio (OR) and its 95% confidence interval to quantify the strength of each association.

2.2.2 *Explanatory Analysis with Machine Learning Models*

Following the exploratory analysis, which established that individual features were significantly associated with correctness, the next step was to investigate their combined and interactive effects. We therefore turned to machine learning models, whose primary function is to learn complex, nonlinear, and interactive patterns from data—relationships that are not captured by the one-to-one statistical tests used in the exploratory phase. The goal of this stage was to construct and validate an explanatory model capable of capturing the underlying relationships between keystroke dynamics and correctness.

We examined several machine learning models, including Logistic Regression, Random Forest, CatBoost, and Support Vector Machine (SVM). Each model was tuned using hyperparameter optimization and evaluated using student-level five-fold cross-validation. This procedure ensured that all responses from a given student appeared exclusively in either the training or test set, thereby providing a robust estimate of generalization to unseen students.

The models were evaluated using a suite of metrics, including the area under the precision-recall curve (AUC-PR), the area under the receiver operating characteristic curve (AUC-ROC), macro-averaged F1-score, balanced accuracy (BACC) and the Matthews correlation coefficient (MCC). Within this explanatory framework, these metrics serve as goodness-of-fit measures, quantifying the extent to which the models successfully learned the underlying relationship between the features and the correctness label. We report the mean and standard deviation of each metric across the five folds to assess both average performance and model stability. Based on this evaluation, Random Forest emerged as the best-performing model and was selected for subsequent analysis.

2.2.3 *Counterfactual Analysis*

Using the validated Random Forest model, the final phase of the analysis focused on interpreting the specific behavioral patterns learned by the model. To achieve this, we employed Diverse Counterfactual Explanations (DiCE) [23]. DiCE is an optimization-based method that generates "what-if" scenarios by identifying the minimal and most plausible feature changes required to flip the model's prediction to a desired class (e.g., from incorrect to correct). Unlike feature-importance methods, which provide global rankings, DiCE yields concrete, instance-level explanations of the patterns

Table 3: Mann–Whitney U test results with Cliff's Delta effect sizes for continuous keystroke features by correctness.

Feature	$\text{Correct}_{\text{Mdn}}$	$\text{Incorrect}_{\text{Mdn}}$	Effect size (δ)	p-value
Average seconds between keys	0.85	0.46	0.35	< 0.001
Seconds per keystroke	1.25	2.33	0.31	< 0.001
Variation in seconds between keys	0.68	0.34	0.30	< 0.001
Keystroke entropy	2.00	2.00	0.13	< 0.001
Keystroke edit distance	1.00	1.00	0.11	< 0.001
Correction density	0.00	0.00	0.07	< 0.001
Correction proportion	0.00	0.00	0.06	< 0.001
Keystroke efficiency ratio	0.75	0.78	-0.06	< 0.001

the model associates with different outcomes. Importantly, it also generates diverse explanations, enabling examination of whether multiple behavioral profiles are associated with correctness.

A key methodological decision was to restrict analysis to verifiable ground-truth cases: true positives and true negatives. Because the model is imperfect, analyzing false positives or false negatives risks interpreting model-specific artifacts rather than stable relationships in the data. By focusing exclusively on cases that the model correctly classified, we ensure that the counterfactual analysis is grounded in the strongest and most reliable portion of the learned signal.

The counterfactual analysis was conducted within the five-fold cross-validation framework. For each fold, we first identified instances belonging to a verifiable group within the test set. For each instance, we generated three diverse counterfactuals, resulting in three distinct hypothetical scenarios per student. Each scenario represents a counterfactual setting in which the student's original feature values are minimally altered to flip the model's prediction. For example, for a true negative instance (incorrect and predicted incorrect), we generated three plausible counterfactuals in which the prediction changed from incorrect to correct.

To ensure plausibility, all counterfactuals were constrained to lie within an allowed range of feature values, defined as the 1st to 99th percentile of the training data for continuous features. We then aggregated the feature changes required to flip predictions. For continuous features, we computed the magnitude of change and analyzed directional proportions, defined as the percentage of changes corresponding to increases versus decreases. For categorical features, we analyzed the proportion of directional transitions (e.g., $0 \rightarrow 1$ or $1 \rightarrow 0$). Directional proportions were averaged across folds to produce a stable final set of results, identifying the feature changes most frequently associated with shifts in correctness.

3. RESULTS

3.1 Feature Association with Correctness

We first examined the relationship between the continuous keystroke features and correctness using the Mann–Whitney U test. The test established statistically significant differences across all eight features for correct versus incorrect responses, as shown in Table 3. Effect sizes (Cliff's Delta) ranged from 0.06 to 0.35, reflecting small to moderate differences across features. For nearly all latency, variability, and correction features, the positive effect sizes indicate that feature values tended to be higher for correct responses than for incorrect ones. The largest effects were observed for *average seconds between keys*, *seconds per keystroke*, and *variation in seconds between keys*. Specifically for these latency features, the effect size range corresponds to a 65% to 68% probability—using a standard derivation of Cliff's Delta—that a randomly selected correct response exhibits a higher feature value than an incorrect response.

Table 4: Fisher's exact test odds ratios (OR) for binary features vs. correctness.

Response:	OR [95% CI]	p-value
FastResponse	**0.03 [0.02, 0.05]**	< 0.001
Pasted	0.35 [0.31, 0.39]	< 0.001
SlowResponse	1.18 [0.96, 1.47]	0.163
WorksheetQuestionHasImage	0.71 [0.67, 0.76]	< 0.001

The Fisher's Exact Test results for the categorical features revealed several significant associations (see Table 4). The largest negative association was observed for *Fast Response* ($\text{OR} = 0.03$, $p < 0.001$). This categorical indicator flagged question transactions completed in five seconds or less and constituted 6% (1,209 transactions) of the total dataset. Questions answered between five seconds and five minutes served as a proxy for normal response time and were used as the comparison baseline. The probability of a fast response transaction being correct was only 1.41%, compared to the baseline correctness rate of 30%. This corresponds to a 95.3% decrease in the probability of a response being correct when completed within five seconds or less.

By contrast, *Slow Response*, defined as responses taking longer than five minutes, constituted 2% of the data (386 transactions) and did not differ statistically from the normal-time baseline ($\text{OR} = 1.18$, $p = 0.163$). Submitting a *Pasted* answer ($\text{OR} = 0.35$) and the presence of an image in the question (*Worksheet Question Has Image*, $\text{OR} = 0.71$) were also significantly associated with lower odds of correctness, though not as strongly as fast responses.

3.2 Impact of Problem Format on Keystroke Patterns

To examine whether problem format itself influenced keystroke patterns, we used the Mann–Whitney U test to compare continuous keystroke features across questions with images versus those without images (Table 5). The analysis revealed statistically significant, but negligible [22], differences in timing behaviors. Timing and variability features, including *average seconds between keys* ($\delta = -0.05$), *variation in seconds between keys* ($\delta = -0.04$), and *keystroke*

Table 5: Mann–Whitney U test comparing continuous keystroke features for questions with images versus those without image.

Feature	With $\text{Image}_{\text{Mdn}}$	No $\text{Image}_{\text{Mdn}}$	Effect Size (δ)	p-value
average seconds between keys	0.54	0.61	-0.05	< 0.001
variation in seconds between keys	0.39	0.44	-0.04	< 0.001
keystroke entropy	2.00	2.00	-0.03	< 0.001
seconds per keystroke	2.84	2.75	0.02	0.073
keystroke efficiency ratio	0.75	0.78	-0.02	0.022
keystroke edit distance	1.00	1.00	-0.01	0.430
correction density	0.00	0.00	-0.01	0.181
correction proportion	0.00	0.00	-0.01	0.261

Table 6: Model performance on predicting correctness from keystroke features. Values are mean ± standard deviation across student-level 5-fold cross-validation.

Model	F1	BACC	AUC	PR	MCC
Logistic Regression	0.44 ± 0.01	0.51 ± 0.00	0.65 ± 0.01	0.39 ± 0.02	0.05 ± 0.01
Random Forest	0.64 ± 0.01	0.69 ± 0.01	0.75 ± 0.00	0.48 ± 0.02	0.35 ± 0.01
CatBoost	0.64 ± 0.01	0.69 ± 0.00	0.75 ± 0.00	0.47 ± 0.02	0.34 ± 0.01
SVM	0.51 ± 0.01	0.53 ± 0.01	0.70 ± 0.01	0.42 ± 0.03	0.10 ± 0.03

entropy ($\delta = -0.03$), were all statistically significantly different between image-based and text-only questions ($p < 0.001$). Given the small effect sizes, these results indicate only slight shifts toward marginally faster and more regular typing on image-based questions—differences that are statistically detectable but practically inconsequential. In contrast, correction-related features ($\delta \approx -0.01$) were not statistically significant (e.g., *keystroke edit distance*, $p = 0.43$), suggesting that problem format did not meaningfully affect the frequency of observable typing errors.

3.3 Counterfactual Explanations of Keystroke Patterns and Correctness

The performance results for the machine-learned models, evaluated using student-level five-fold cross-validation, are presented in Table 6. Ensemble methods (Random Forest and CatBoost) substantially outperformed the simpler Logistic Regression and Support Vector Machine models across all evaluation metrics. The Random Forest classifier was selected for further analysis due to its *relatively* robust performance, achieving the highest or joint-highest score on every metric.

Given that the baseline for random guessing in this imbalanced dataset is the prevalence of the minority class (approximately 0.28 for the precision-recall AUC baseline), the Random Forest's mean precision-recall AUC of 0.48±0.02 indicates that the model learned a moderate, generalizable signal. The balanced accuracy of 0.69 further suggests reasonable discrimination between correct and incorrect responses, corroborated by a Matthews Correlation Coefficient of 0.35. This validated Random Forest model served as the basis for the subsequent counterfactual analysis.

We used DiCE to interpret the validated Random Forest model, identifying the keystroke pattern adjustments required to change verifiably incorrect answers (true negatives) into correct ones, as well as the adjustments required to change verifiably correct answers (true positives) into incorrect ones. For the true negatives, the analysis of continuous features (Table 7) consistently showed that the model required positive-direction adjustments (increase) across all features in order to flip an incorrect prediction to correct. This finding aligns with the correlational analysis, which showed that correct responses generally exhibited higher values for nearly all continuous keystroke features. The most frequently adjusted features were timing-related: *seconds per keystroke* (30.4% of all counterfactuals) and *average seconds between keys* (25.8%). The largest median adjustments included an increase of 34.1 units for seconds per keystroke and 8.3 units for average seconds between keys. Editing and variability features were also adjusted, with *keystroke entropy* modified in 9.31% of counterfactuals (median change = 1.67) and *keystroke edit distance* in 4.89% (median change = 26.0).

The analysis of categorical transitions (Table 8) revealed that the most frequent binary change required was transitioning *Fast Response* from 1 to 0, occurring in 5.69% of all counterfactuals. This directly corroborates the strong negative association observed in the exploratory analysis. Additionally, the question format feature *Worksheet Question Has Image* was required to change from present to absent in 2.37% of counterfactuals. Other categorical transitions occurred less frequently.

The analysis of true positives identified the minimal feature adjustments required to change a verifiably correct response into an incorrect one (Tables 9 and 10). These results largely mirror the true negative findings in reverse. For continuous features, the most frequent change was a decrease in *keystroke entropy* (20.20% of counterfactuals, median change = −1.74). For categorical features, the most frequent transition was changing *Fast Response* from 0 to 1, which occurred in 18.4% of counterfactuals. This indicates that shifting a response from non-fast (i.e., baseline) to fast was often sufficient for the model to flip a correct prediction to incorrect. Consistent with the true negative results, changing *Worksheet Question Has Image* from absent to present occurred in 1.86% of counterfactuals. Also, transitioning *Pasted* from 0 to 1 occurred in 2.67% of cases.

Table 7: Directional changes in continuous features required to turn answers that were incorrect into answers that become correct for true negatives (TN, 0→1 counterfactuals).

Feature	Proportion Increased(%) ↑	Proportion Decreased(%) ↓	Median ↑	Median ↓
average seconds between keys	**25.82**	0.15	8.31	-10.12

4. DISCUSSION

The central question motivating this study was whether keystroke dynamics captured unobtrusively during authentic mathematics problem solving can reliably differentiate between correct and incorrect responses. Our findings provide evidence that they can: across 21,938 open-ended responses, students who answered correctly exhibited systematically different typing behaviors than those who answered incorrectly. These differences emerged consistently across multiple analytical approaches (statistical comparisons, machine-learned models of the underlying relationships, and counterfactual interpretations of those learned patterns), suggesting that the temporal and behavioral traces left during response construction carry meaningful information about problem-solving success.

Correct responses were characterized by longer inter-keystroke intervals, greater variability in typing pace, and more frequent revision activity. Effect sizes ranged from small to moderate (Cliff's $\delta = 0.06$ to 0.35), with timing-based features showing the strongest associations. Students who typed more slowly and irregularly (pausing between keys, varying their pace, and editing their work) were more likely to submit correct answers than those who typed quickly and smoothly. What might account for these patterns? One interpretation is that slower, more variable typing reflects cognitive work happening between keystrokes: mental calculation, strategic deliberation, checking of intermediate results, or reconsideration of solution approaches. This interpretation aligns with theoretical accounts suggesting that keystroke-level information can shed light on cognitive and metacognitive processes involved in problem solving [15]. Long pauses may reflect planning or recall, while patterns of editing and revision may indicate monitoring and self-correction (behaviors associated with deliberate engagement). This interpretation is consistent with broader findings that deliberation and reflection are associated with better problem-solving outcomes. For instance, Chan et al. [8] found that middle-school students who paused longer before beginning to solve algebra problems in a learning game employed more efficient strategies, suggesting that taking time to think enhances performance. While their work examined pre-solving deliberation, our findings suggest that deliberation manifested during response construction (as slower, more variable typing with revision) similarly relates to success in open-ended mathematics problem solving.

Our results also align with work demonstrating relationships between keystroke patterns and performance outcomes across domains. In writing research, keystroke features such as revision frequency and timing have been linked to text quality [3, 38], with revision and pausing patterns differentiating more and less successful writers. In programming education, keystroke features including code editing patterns have proven informative for identifying at-risk students [7]. These findings extend to mathematics problem solving, demonstrating that typing dynamics capture aspects of cognitive engagement even in relatively brief, open-ended responses. The convergence of findings across writing, programming,and mathematics suggests that keystroke patterns may reflect domain-general characteristics of deliberate, monitored performance.

However, keystroke data present an inherent interpretive challenge. Unlike verbal protocols that provide direct access to students' articulated thoughts, or eye-tracking that reveals attentional focus, keystroke logs offer only indirect behavioral evidence. A pause between keystrokes might indicate careful checking, but it also could indicate retrieval difficulty, distraction, or indecision; the data alone cannot distinguish these possibilities. Moreover, both slower typing and correct answers could be independently caused by stronger mathematical knowledge or by better self-regulation skills. Students who understand the material well might type more deliberately because they recognize the importance of checking their work, while simultaneously being more likely to arrive at correct solutions due to superior domain knowledge.

While the continuous keystroke features showed moderate associations with correctness, we observed that one categorical threshold emerged with a particularly strong association: responses completed in five seconds or less were correct only 1.41% of the time, compared to a baseline rate of 30% for responses taking between five seconds and five minutes. This

Table 9: Directional changes in continuous features required to turn answers that were correct into answers that become incorrect for true positives (TP, 1→0 counterfactuals).

Feature	Proportion Increased(%) ↑	Proportion Decreased(%) ↓	Median ↑	Median ↓
average seconds between keys	5.63	1.98	9.46	-0.94

WorksheetQuestionHasImage	1→0	0.37

represents a 95.3% reduction in the probability of correctness. This pattern is consistent with prior work demonstrating that extremely rapid responses in digital learning environments signal disengagement rather than genuine problem solving [6, 10, 41]. For instance, Beck [6] observed that extremely rapid responses in a reading tutor corresponded to chance-level performance, indicating students were guessing rather than genuinely processing the questions. Similarly, Cocea and Weibelzahl [10] found that rapid progression through learning materials without adequate time for comprehension reliably signaled disengagement across multiple e-learning platforms. Wright [41] reached comparable conclusions in non-timed formative assessments, demonstrating that responses completed in under five seconds often reflected guessing behavior that added error to ability estimates. Our results align with and extend these findings to open-ended mathematics problem solving: five seconds appears insufficient for the cognitive processes required to meaningfully engage with questions that demand calculation and written explanation. Students completing problems this quickly are almost certainly not progressing through the stages identified in classical models of mathematical problem solving (understanding, devising a plan, executing, and checking; [27, 32]). Rather, these extremely rapid responses likely represent giving up, guessing, entering placeholder text, or pattern-matching without comprehension. This stands in contrast to the deliberate engagement our data suggest characterizes successful problem solving, where students invest time in thinking through problems rather than rushing to submit responses.

The results from the counterfactual analysis further reinforced the centrality of this threshold in the model's learned patterns. When examining what minimal changes would flip the model's classification of an incorrect response to correct, moving students out of the fast response category occurred in 5.69% of counterfactuals. Conversely, for correct responses, transitioning into the fast response category was required in 18.4% of cases to flip the classification to incorrect, the single most common categorical change. This suggests that the five-second threshold captures a qualitatively different mode of engagement that the model learned to strongly associate with failure. Interestingly, the pattern was asymmetric for time outliers. While extremely fast responses were strongly associated with failure, extremely slow responses (greater than 5 minutes) showed no significant difference from baseline correctness. This asymmetry implies a minimum engagement threshold necessary for success (rushing through problems in seconds is almost universally associated with failure), but that additional time beyond approximately five minutes offers no systematic advantage. While deliberation is necessary, time alone does not ensure success.

Initially, we had hypothesized that problem format might influence keystroke behavior. Students responding to questions containing diagrams might type differently than those responding to text-only problems (perhaps pausing more frequently to inspect visual information or exhibiting altered pacing due to the cognitive demands of integrating visual and symbolic content). Prior research has shown that diagrams can substantially affect problem-solving strategies and performance in mathematics [9], and theories of problem representation emphasize that format fundamentally shapes solution approaches [20]. In this study, however, the keystroke patterns showed minimal variation across formats. While statistically significant differences emerged between image-based and text-only questions, effect sizes were negligible ($\delta = -0.01$ to -0.05). Students typed marginally faster and more regularly on image-based questions, but these differences were practically trivial. Correction behaviors showed no significant variation across formats.

Problem format was, however, associated with correctness. Image-based questions had lower odds of correctness (OR = 0.71, $p < 0.001$), and the counterfactual analysis supported this pattern. For incorrect responses, changing "Worksheet Question Has Image" from present to absent occurred in 2.37% of counterfactuals needed to flip the model's classification to correct. For correct responses, changing from absent to present occurred in 1.86% of counterfactuals needed to flip classifications to incorrect. The model learned that image presence was associated with lower correctness. This may be because these types of problems were less familiar to students, or because translating information across formats was difficult for these students. Overall, though, while images were associated with lower correctness, they do not appear to meaningfully change how students type their re-

sponses.

The machine learning models helped us better understand the full complexity of the relationships between keystroke features and correctness. The Random Forest model achieved reasonable goodness-of-fit (balanced accuracy = 0.69, MCC = 0.35, AUC-PR = 0.48), indicating that it successfully learned a meaningful signal from the data. These metrics provide evidence that the model identified stable, generalizable patterns in the relationship between typing behavior and problem-solving success. This level of performance is comparable to prior work using keystroke features for educational prediction. For instance, Casey [7] found that keystroke features improved models for identifying at-risk programming students, though with similarly modest improvements over baselines. Conijn et al. [11] reported that keystroke-based models for predicting essay quality achieved only modest gains over baseline models. Our results follow this pattern: keystroke dynamics provide meaningful but incomplete signals about outcomes, suggesting that typing behavior captures some (but not all) of the factors that differentiate success from failure.

To understand the structure of these learned relationships, we again employed counterfactual analysis. For incorrect responses (true negatives), the most frequently required adjustments involved increasing timing features, particularly seconds per keystroke (median increase: 34.1 units, modified in 30.4% of counterfactuals) and average seconds between keys (median increase: 8.3 units, modified in 25.8% of counterfactuals). For correct responses (true positives), the most common changes involved decreasing keystroke entropy (median decrease: 1.74, modified in 20.2% of counterfactuals). The model therefore found that deliberate, unhurried response construction is systematically associated with correctness, while rapid, streamlined typing is associated with failure. Interpreting these counterfactuals requires care. They reveal what the model learned about the relationship between keystroke patterns and correctness (which features it weighted most heavily and what magnitude of change it considers decision-relevant) but they do not establish causal pathways or prescribe interventions. The finding that increasing seconds per keystroke by 34 units would flip many model classifications does not imply that instructing students to "type slower" would improve their answers. Instead, this association may be mediated by unmeasured cognitive processes. Slower typing might be a consequence of deeper engagement rather than a cause of it. In general, the value of counterfactual analysis lies in revealing the structure of learned relationships and identifying behavioral thresholds that most strongly differentiate success from failure. The prominence of the fast response transition and timing-related features in counterfactual examination of the Random Forest model accords with the statistical analysis and provides additional confidence that these aspects of typing behavior mark meaningful distinctions in problem-solving processes.

4.1 Limitations

Several limitations should be noted. First, our outcome measure was binary correctness, which does not capture partial understanding or the quality of reasoning. A student might produce an incorrect answer due to a minor arithmetic error despite demonstrating sound problem-solving strategies, while another might guess correctly without genuine understanding [12]. Keystroke patterns may differentially relate to these scenarios, but our analysis treated all incorrect responses the same and all correct responses the same.

Second, our counterfactual analysis relied on a machine-learned model (Random Forest) as a representation of the relationship between keystroke patterns and correctness. While this model demonstrated reasonable goodness-of-fit, it likely did not capture all relevant dependencies or interactions. The counterfactuals generated by DiCE reflect what the model learned about the data, not necessarily the true underlying relationships. Our focus on verifiable ground-truth cases (true positives and true negatives) mitigates this concern by ensuring we interpret only the strongest part of the learned signal, but the possibility remains that some identified patterns are model-specific rather than reflecting genuine behavior–outcome relationships. Replication using different modeling approaches could potentially increase certainty about these findings.

Third, the explanatory models we developed capture associations between keystroke patterns and correctness but do not establish causation. We cannot determine from these analyses whether deliberate typing behaviors contribute to correct problem solving, whether both are products of underlying cognitive or motivational factors, or whether the relationship is bidirectional.

Finally, while this study found that problem format (image-based versus text-only) did not meaningfully affect keystroke patterns, this finding should be interpreted with caution. We examined only one dimension of format variation (presence or absence of a single static image), which does not capture the full range of visual complexity that affects problem solving. Images in our dataset varied widely in their content and informational value, yet our current analysis treated all image-based problems as equivalent. More broadly, the format invariance we observed may reflect the specific nature of our dataset rather than a general principle, and the boundary conditions under which keystroke patterns remain stable across task variations remain to be established through more systematic investigation of problem characteristics.

4.2 Future Directions

While our study is fundamentally explanatory rather than predictive or interventional, the patterns we identified may inform future work in several directions. The fast response threshold, in particular, emerges as a robust behavioral marker that could potentially serve as a trigger for lightweight prompts asking students to reflect before submitting [5]. The broader pattern—that slower, more variable, more effortful typing is associated with correctness—suggests that learning environments should encourage deliberation rather than rapid response entry. However, implementing such features would require careful validation, as we cannot assume that prompting students to engage in behaviors associated with success will actually improve their performance (e.g., Roll et al. [29]).

Future research could address several limitations and open questions. First, combining keystroke data with other pro-

cess measures—such as embedded probes asking students to explain their thinking, concurrent eye-tracking, or retrospective interviews—could help map particular keystroke patterns onto specific cognitive activities and disambiguate the interpretive ambiguity inherent in behavioral traces. Second, examining whether keystroke dynamics are associated with different types of errors (conceptual vs. procedural, early-stage vs. late-stage) or different qualities of correct responses (well-reasoned vs. lucky guesses, perhaps inferred through a contextual guessing model—e.g., Baker et al. [4]) could provide more nuanced understanding than our binary correctness measure allows.

Finally, cross-context replication would strengthen confidence in generalizability. Our dataset came from a single online mathematics platform serving middle school students; the extent to which these findings apply to other age groups, content areas, or learning environments remains uncertain. Different mathematical topics, problem structures, and student populations might produce different relationships between keystrokes and other constructs.

4.3 Conclusion

Keystroke dynamics reliably differentiate correct from incorrect responses in mathematics problem solving. Students who answered correctly typed more slowly, with greater variability and more frequent revision, compared to those who answered incorrectly. The strongest association involved responses completed in under five seconds, which were correct less than 2% of the time. While problem format (image versus text) was associated with correctness, it did not meaningfully affect keystroke patterns, suggesting that the behavioral indicators we identified may be reliable process signals even across different problem presentation formats. Machine learning models successfully learned the complex relationships between keystroke features and correctness (balanced accuracy = 0.69, MCC = 0.35), and counterfactual analysis revealed that timing-related features and the fast response threshold were the most decision-relevant factors in the model's representation. These findings demonstrate that keystroke logging can reveal meaningful signals about problem-solving processes. Our results extend prior work showing that keystroke patterns inform predictions of educational outcomes, demonstrating that typing dynamics also differentiate immediate problem-solving success in mathematics. While interpretive ambiguity remains regarding the specific cognitive processes underlying different typing patterns, and causal relationships cannot be established from these analyses, this work provides empirical evidence that fine-grained behavioral traces differentiate successful from unsuccessful mathematical problem solving. Future work combining multiple process-tracing methods, exploring intervention designs, and testing generalization across contexts can build on this foundation to deepen understanding of how students think through mathematics problems.

ABSTRACT

As the world becomes increasingly saturated with AI-generated content, disinformation, and algorithmic persuasion, critical thinking – the capacity to evaluate evidence, detect unreliable claims, and exercise independent judgment – is becoming a defining human skill. Developing critical thinking skills through timely assessment and feedback is crucial; however, there has not been extensive work in educational data mining on defining, measuring, and supporting critical thinking. In this paper, we investigate the feasibility of measuring "subskills" that underlie critical thinking. We ground our work in an authentic task where students operationalize critical thinking by writing argumentative essays. We developed a coding rubric based on an established skills progression and completed human coding for a corpus of student essays. We then evaluated three distinct approaches to automated scoring: zero-shot prompting, few-shot prompting, and supervised fine-tuning, implemented across three large language models (GPT-5, Llama 3.1 8B, and ModernBERT). Fine-tuning Llama 3.1 8B achieved the best results and demonstrated particular strength on subskills with highly separable proficiency levels with balanced labels across levels, while lower performance was observed for subskills that required detection of subtle distinctions between proficiency levels or imbalanced labels. Our exploratory work represents an initial step toward scalable assessment of critical thinking skills across authentic educational contexts. Future research should continue to combine automated critical thinking assessment with human validation to more accurately detect and measure dynamic, higher-order thinking skills.

1. INTRODUCTION

While the ability to think critically has always been an important skill for students to learn, it is increasingly important in today's ever-changing world [14]. Despite widespread recognition of its significance, the development of students' critical thinking has not been a major focus in the educational data mining (EDM) community to date. For example, a search of yearly EDM Conference Proceedings since 2020 revealed only one title and zero abstracts with the term 'critical thinking.'

There are likely several reasons why critical thinking has not been a central focus in educational data mining. Typically, in the EDM community, we must be able to create reasonably accurate ways to assess a skill or construct in order to either proactively or reactively respond to support the learner in a personalized way. Before a construct can be assessed, it must be clearly defined and operationalized, which has been a challenge for critical thinking skills to date. For example, a number of competing definitions and frameworks have articulated distinct visions of what critical thinking is, and how it manifests across contexts [33, 46, 60]. A limitation of many of these prior definitions and frameworks is that they have been vague and difficult to operationalize [4, 5]; others have been criticized for being narrow and over-simplified [57].

A recent definition of critical thinking that is both specific and feasible to operationalize comes from Pasquinelli and colleagues: critical thinking is "the capacity of assessing the epistemic quality of available information and—as a consequence of this assessment—of calibrating one's confidence in order to act upon such information" [46]. Within such a framework, we can think of critical thinking in terms of skills that can be demonstrated, processes needed to effectively use these skills in specific situations, and dispositions that motivate the use of these skills when needed [24]. Critical thinking is, of course, complex and multi-dimensional; successful critical thinking in context calls on skills such as understanding and analyzing information, evaluating evidence, making inferences, articulating one's own arguments, and monitoring one's own thinking process [17, 19, 24, 33, 47]. It's also worth noting that an open question is whether critical thinking skills are domain-general or domain-specific [15, 33, 41, 46]. For this particular submission, we operationalize a set of core "subskills" that are primarily involved in domains that support evaluating and synthesizing information to form new opinions as a foundational example for how to support such modeling.

A key step towards being able to support critical thinking more effectively is being able to assess it rapidly and in context to inform teachers and students [16] as well as adaptive learning platforms. Critical thinking assessments have been developed in multiple formats (e.g., multiple choice, open-ended questions), but these measurements have faced challenges with reliability and validity [33, 37]. Another important limitation to address is the scarcity of assessments that are easily implemented and actionable within educational settings [37]. Developing tools that can detect indicators of critical thinking skills in the moment and automatically, particularly in the context of authentic learning activities, could increase the feasibility for use in adaptive learning and contribute to formative assessment for teachers.

In the current paper, we provide insights into this problem by investigating the feasibility of measuring a set of critical thinking subskills that are core to critical thinking processes (e.g., evaluating evidence, drawing conclusions), rapidly and solely from an artifact produced by an authentic student learning activity, an argumentative essay. We developed a rubric for coding critical thinking subskills based on an existing skills progression, which human raters used to score a set of argumentative essays. We then explored the use of large language models (LLMs) in assessing critical thinking subskills from student-written argumentative essays. We investigated a range of methods, from prompting to fine-tuning, across three different LLMs, leveraging the same rubrics we provided the human coders.

Ultimately, we aim to develop methods that can be used to assess critical thinking within authentic learning activities, across educational activities and contexts. For this paper, we began with a single context (essays) and multiple subskills, providing a proof-of-concept methodology for EDM. We attempted to embrace the inherent complexity of critical thinking, in that it has multiple subskills that exist long a progression rather than being easily operationalized and modeled in a binary manner. Our goal was therefore to test whether we could develop effective models for the present dataset, and which subskills (if any) were amenable to such detection.

2. RELATED WORK

2.1 Critical Thinking Definitions and Frameworks

As mentioned above, there have been a range of definitions and frameworks for critical thinking [1, 46, 52, 60], but across definitions and frameworks, critical thinking generally involves having the appropriate background knowledge or acquiring information as needed [33], being motivated to engage in critical thinking processes [17, 24], possessing essential critical thinking competencies [19, 57], and being able to use the right competencies for a specific situation in the right fashion [7, 57]. While many frameworks for critical thinking skills exist (see reviews in [1, 33]), and there are many important differences between these frameworks, there are some subskills which the field has come to a consensus about. First, critical thinking involves evaluating the quality and credibility of information (e.g., source, evidence, argument) [17, 19, 30, 33, 47], analyzing the meaning of this information [17, 19, 24, 33, 47], and making inferences, such as how the information might apply in new scenarios [17, 19, 33]. Critical thinking also involves formulating one's own arguments [31], explaining one's own reasoning [17, 19, 33], and forming conclusions [47]. Finally, critical thinkers necessarily self-regulate their processes to continuously monitor and improve [17, 19, 24, 30, 33, 47]. Here we focus on these subskills rather than the overall construct of "critical thinking" in order to target the process involved in a more concrete and definable way.

2.2 Measuring Critical Thinking

Regardless of the ongoing debates on definitions and frameworks, there have been several attempts to measure critical thinking skills over the last three decades [8, 16, 33, 37]. The simplest approach to assessing critical thinking has been to give scenarios to students and then ask multiple choice questions [10, 62]. While these assessments can be time efficient, and can have good psychometric properties, there have been concerns about how much information they provide about critical thinking for real-world challenges and authentic activities [37], particularly in a way that can be used to support formative feedback.

Some assessments, such as the Halpern Critical Thinking Assessment [23], have attempted to use open response items and are more relevant to real world situations, where students need to respond authentically in the moment [37]. Still other instruments and rubrics have been used to assess critical thinking in artifacts [16, 20, 37]. For example, the Ennis Weir Critical Thinking Essay Test [18] was designed to assess critical thinking in a more realistic way by asking

participants to respond to a fictional argumentative letter. Another example, the Holistic Critical Thinking Scoring Rubric [20], can be used to assess critical thinking as demonstrated in an essay or presentation, whether authentic or designed for the purpose of assessment. However, instruments would ideally give students opportunities to develop skills in authentic learning contexts with quick and accurate AI-supported feedback.

2.3 Automated Essay Scoring and Qualitative Coding Approaches

One possible paradigm for how to address this may come from recent work in two areas: automated essay scoring (AES) and automated qualitative coding. AES has been studied for decades, with early approaches relying on surface features such as word counts, lexical diversity, and syntactic patterns to approximate human scoring [2, 48]. Then, neural and transformer-based models shifted the field toward more robust representations of text, enabling AES systems to capture deeper discourse and linguistic patterns [27, 51]. Most recently, large language models (LLMs) have introduced a new approach that does not require training: one can prompt LLMs with hand-crafted scoring rubrics and ask them to estimate the score of an essay (see review in [35]). Similar approaches using prompting of LLMs have been used to assess complex reasoning in shorter text as well [38, 58, 65], building on past work that used previous-generation natural language processing (NLP) techniques [28]. This progression has broadened the scope of automated assessment of text from holistic proficiency measures toward more fine-grained, rubric-aligned scoring tasks.

Recent studies have leveraged AES and automated qualitative coding methods for a number of purposes, and have investigated both their potential and limitations. For example, Xiao et al. [65] introduced a dual-process framework for human-AI collaborative essay scoring, leveraging LLMs to provide both initial predictions and justifications that can support teacher decision-making. Stahl et al. [56] demonstrated that integrating argument mining outputs into transformer-based models can enhance AES and provide a stronger basis for modeling reasoning skills. At the same time, Seßler et al. [53] compared LLM performance with teacher ratings in multidimensional essay scoring, showing that while models achieve promising agreement with human judgments, important gaps remain in transparency and trait sensitivity. Similarly, Liu and colleagues [38] investigated the strengths and weaknesses of different prompting techniques for three different textual data sets, and Simon and colleagues [54] investigated how multi-agent LLM systems could enhance the performance of automated coding for thematic analysis.

Early steps have already been taken to utilize this type of method for aspects of critical thinking. For example, early systems applied previous-generation NLP methods such as Latent Semantic Analysis (LSA) to open-ended responses to capture aspects of argumentation such as the relevance of an argument and the effective use of knowledge [49, 50], demonstrating potential but limited alignment with human judgments. More recently Yeginbergen et al. [66] introduced a framework for counter-argument generation that combines retrieved external evidence with LLM prompting and evaluates outputs using an LLM-as-a-Judge metric, advancing critical thinking assessment toward more evidence-grounded and generative application. These approaches show the possibility of using natural language processing to study and assess critical thinking in authentic or similar artifacts, but have not yet been successful at assessing critical thinking multi-dimensionally, in a fine-grained fashion, and across educational activities and contexts. Thus, while our task is not AES in the conventional sense of scoring overall writing quality, it is closely related methodologically: we similarly evaluate whether automated systems can assign human-aligned rubric scores to student essays, but we shift the scoring target from writing quality to critical thinking subskills.

3. METHOD

3.1 Dataset

We used a portion of the PERSUADE 2.0 corpus [11] that was made publicly available as part of the Feedback Prize - Predicting Effective Arguments competition [21] in our work. The PERSUADE 2.0 corpus includes more than 25,000 argumentative essays that were written by 6th to 12th grade students in the United States, for 15 prompts on two writing tasks: independent and source-based writing. The training data that was released as part of the competition included 4,115 essays from the original corpus. We did not have access to the essay prompt, writing task, or source materials (in the case of source-based writing) in the publicly available dataset, and therefore did not use this information in our human or LLM coding. We selected this dataset as an initial use case for the development of a critical thinking model since argumentative essays (and argumentation more generally) often include evidence of critical thinking processes (e.g., providing evidence for a claim, evaluating alternative viewpoints through counterarguments).

3.2 Critical Thinking Rubric

We developed a rubric for coding critical thinking based on an early version of the Critical Thinking Progression for High School Students developed by the Skills for the Future (SFF) initiative, a partnership between ETS and The Carnegie Foundation for the Advancement of Teaching [55].[1] The progression defined critical thinking as "the skill and disposition to actively seek and evaluate information and construct evidence-based arguments to reach well-founded conclusions or informed decisions, including recognizing and applying sound logical reasoning. It plays an important role in learning activities, such as evaluating multiple sources, identifying assumptions and reasoning flaws, and making sound arguments. Developing strong critical thinking skills enables students to tackle complex challenges more effectively and achieve greater learning outcomes" [55].

The skills progression included four skills that were further specified into subskills. The first skill, *Information Seeking*, was not included, as the focal dataset for the present work was completed essays. The remaining three skills were retained for the present work and are shown in Table 1. While these three skills were identified from the SFF initiative, we grounded the subskills in our literature review. For example, many definitions of critical thinking include the ability to determine the trustworthiness of information [17, 19, 30, 33, 47], otherwise known as *Evaluating Evidence Strength* in SFF.

[1] The current version of the Skills for the Future Progressions were made public in January 2026 (https://www.ets.org/newsroom/ets-carnegie-release-skills-progressions.html). They have four levels intended for understanding skill acquisition during secondary school. The project continues to iterate on ways to portray the ways in which skill development is not linear and is currently working to validate these progressions with educators and students.

Table 1. Critical thinking subskills

Skill	Subskill	Definition	Example
2: Information Analysis	2.1 Synthesizing Multiple Sources	Effectively synthesizes multiple pieces of information	Summarizes information from multiple sources (with citations) but does not integrate information
	2.2 Evaluating Evidence Strength	Evaluates the strength and relevance of evidence used to form a conclusion	Presents evidence and links evidence to a specific conclusion, but does not evaluate the relevance or strength of the evidence for the argument generated
3: Argument Generation	3.1 Using Counterarguments	Effectively addresses counterarguments	Acknowledges specific opposing viewpoint(s), counterargument(s), or qualifier(s)
	3.2 Using Facts and Opinions	Relies on data and/or facts over opinions	Uses facts and opinions about equally to support claim(s) and/or arguments
4: Logical Reasoning	4.1 Drawing Conclusions	Draws specific conclusions	Draws a specific conclusion to analyze simple and straight-forward relationships/argumentations
	4.2 Using Logical Fallacies	Recognizes and avoids logical fallacies	Uses logical fallacies and evidence about equally when generating arguments

Three proficiency levels were included in the original progression: 'Emerging' (representing lowest level of proficiency, where students are "beginning to identify and understand key aspects of critical thinking"), 'Expanding' ("developing [critical thinking] skills"), and 'Exemplifying' ("demonstrating proficiency" and mastery of critical thinking skills). After initially exploring the feasibility of using the progression for our desired purposes quantitatively and qualitatively, we decided to add two proficiency levels to the rubric that demonstrated lower proficiencies than the 'Emerging' level: 'Below Emerging' (where essays did not yet meet the threshold for 'Emerging' criteria) and 'Not Applicable' (the lowest proficiency level, where "certain critical thinking elements are absent from student contribution," which inhibits a proficiency rating").

We also adjusted the criteria across subskills for achieving various proficiency levels. First, we adjusted the progression to increase clarity in coding and reduce cognitive load of coders, such as collapsing across two sections for each subskill, using parallel wording across proficiency levels, and making relative rather than numerical statements (e.g., "Uses more opinions than facts," "Uses more logical fallacies than evidence"). Second, rather than modifying the progression directly, we provided additional context, such as by broadening the criteria for citing sources in *Synthesizing Multiple Sources* (e.g., direct quotes, reference to author, title of a text) and re-defining evidence in *Evaluating Evidence Strength* (e.g., anything used to support a claim, which can include both facts and opinions/anecdotes).

Third, we made distinctions between certain subskills (i.e., to avoid essays being scored at lower proficiency levels in multiple subskills for the same mistake) while also connecting subskills to align greater critical thinking with better quality arguments. For example, it was necessary for writers to have a clear conclusion (*Drawing Conclusions*) to connect evidence to the conclusion (*Evaluating Evidence Strength*) and evaluate the presence and quality of counterarguments (*Using Counterarguments*). Ultimately, the final rubric included five proficiency levels (from 'Not Applicable' to 'Exemplifying'), three skills and six subskills, and various definitions and resources to support the coding process.

3.3 Human Coding

3.3.1 Coders and Codebook

The original coders were four graduate students at a large university in the U.S. (Coder Group 1). All coders had Master's degrees and were advanced students (fourth through sixth years) in an educational psychology PhD program. Their engagement included three meetings to achieve sufficient reliability and independent coding of 50 essays (200 essays total). The codebook development primarily focused on adapting the original Critical Thinking Progression into a rubric that could be applied to coding a specific student-generated artifact (e.g., essay), which is detailed previously in Section 3.2. However, the need for supplementary information was identified during the codebook development and initial training meetings with coders. For example, clarification was needed for *Synthesizing Multiple Sources* as to what qualified as a citation since the essays were written by grade 6–12 students and how to discriminate between summarizing and integrating multiple sources.

A second group of coders (Coder Group 2) was recruited to expand our sample of human-coded essays. Coder Group 2 included three graduate students, two of which were from another large university in the U.S. and one from a large university in Australia. All coders had Master's degrees, and one was in the final year of another Master's program. All coders had extensive prior experience with qualitative coding. Their engagement included three meetings to achieve sufficient reliability and independent coding of 100 essays (300 essays total). The final codebook that was used for Coder Group 1 was used for Coder Group 2 with no additional modifications.

3.3.2 Reliability

Given the complexity of critical thinking as a construct and our overarching goal for this work as usable in practice (i.e., build a critical thinking model that can be used for similar purposes to iteratively evaluate AI tools), we decided on a level of reliability consistent with our preliminary work. Therefore, we did not use the typical thresholds for evaluation criteria for achieving interrater reliability for Coder Group 1 (e.g., Krippendorff's $\alpha \geq .8$) [29, 40, 63]. Instead, we set our threshold to a Krippendorff's Alpha greater than or equal to .6 as our criteria for sufficient interrater reliability. We adopted Krippendorff's Alpha as we had four coders who during the process of achieving reliability provided ordinal codes for

all subskills in all essays [25]. The coders scored each subskill holistically by providing a single rating for each subskill for each essay. We used the K-Alpha Calculator [40] to compute Krippendorff's Alpha for each subskill in each attempt to achieve sufficient interrater reliability, described next.

Two rounds of coding were required to achieve sufficient interrater reliability for Coder Group 1, and each round adopted the same approach. Coders were asked to code 10 essays for all six subskills (see Table 1). Prior to the first round of coding, coders engaged in a 90-minute training session. During this session, they also coded an essay collaboratively as a group. The coders engaged in a 60-minute disagreement resolution session that reviewed disagreements in round one codes as well as identified instances in which rubric revisions were necessary (see Section 3.2). The coders then completed a second round of coding with new essays that were coded for all six subskills. The second round of coding resulted in sufficient reliability for all subskills (Table 2), which exceeded our pre-defined threshold for sufficient reliability ($\alpha \geq .60$) and generally achieved a satisfactory level of agreement [40]. The one exception was *Using Facts and Opinions*, which did not reach our pre-defined threshold for sufficient reliability. We chose to proceed with coding of *Using Facts and Opinions* as the discussion of coder disagreements revealed that the disagreements generally stemmed from the coders not having access to the source material provided to students when writing the essays to determine whether statements were fact or opinion. Since our goal was to explore whether it was possible to engage in the process of defining, coding, and predicting critical thinking indicators (rather than develop the most "effective" model), we concluded the interrater reliability had reached a sufficient level to proceed.

Table 2. Reliability for human coder Group 1 and Group 2

Skill	Coder Group 1 Krippendorf's Alpha	Coder Group 2 Weighted Kappa *M (Min-Max)*
Synthesizing Multiple Sources	1.00	0.87 (0.79-0.91)
Evaluating Evidence Strength	0.68	0.74 (0.66-0.78)
Using Counterarguments	0.70	0.72 (0.65-0.78)
Using Facts and Opinions	0.57	0.82 (0.80-0.83)
Drawing Conclusions	0.75	0.69 (0.55-0.80)
Using Logical Fallacies	0.79	0.79 (0.69-0.84)

Although reliability was achieved after the second round, coders met for another 60-minute session, where additional revisions to the rubric were made based on coder disagreement and feedback (see Section 3.2). Then, each coder was assigned 50 essays to independently code for each of the six subskills, which resulted in 200 human-coded essays (5% of total essay sample).

Based on initial model performance, we determined that additional human-coded essays were necessary. Coder Group 2 engaged in the same 90-minute training session as Coder Group 1 and then proceeded to achieve reliability. Given that the goal was to increase the sample of human-coded essays, Coder Group 2 did not seek to achieve sufficient reliability within their group but rather to achieve sufficient reliability with Coder Group 1. This meant that essays coded by Coder Group 1 were leveraged for Coder Group 2 reliability along with the final version of the rubric and that reliability was computed between each coder from Coder Group 2 with Coder Group 1 codes. Weighted Kappas (Quadratic) were used for evaluating interrater reliability with the same threshold used for Coder Group 1 ($\alpha \geq 0.6$). Two rounds of coding (with a 60-minute meeting after each round) were required to achieve sufficient interrater reliability for each Coder Group 2 coder for each subskill (Table 2), except for one coder slightly below our threshold for *Drawing Conclusions* (*Kappa* = .55). Coders were then each assigned 100 essays to independently code for each subskill, which resulted in an additional 300 essays (7% of total essay sample).

The total human-coded essay sample included 500 essays (12% of total essay sample) that were used to evaluate the performance of the LLM critical thinking model. While we recognize this is a modest number of human-coded essays given the nuanced and multifaceted nature of critical thinking and its operationalization, the number is consistent with the overall exploratory goal of this work. Additionally, the sample size is in the range commonly used in other research involving evaluations of whether LLMs agree with human codes [6, 9, 38, 43, 45].

3.4 LLM-based Assessment

We evaluated two complementary approaches for LLM-based critical thinking assessment: (1) prompting proprietary LLMs, specifically OpenAI's GPT-5, and (2) fine-tuning two open-source models for classification purposes, Llama 3.1 8B [22] and ModernBERT [61], on our student essay dataset.

3.4.1 Prompting and Fine-tuning

We prompted GPT-5, a state-of-the-art LLM at the time of this work, with two settings: *zero-shot* [34] and *few-shot* [65]. In both settings, we instructed the LLM to assume the role of a calibrated educational scorer, tasked with classifying essays on fine-grained critical thinking subskills according to our structured rubric. The prompt included: (a) the general definitions of the five proficiency levels (0 = 'Not Applicable' through 4 = 'Exemplifying'), and (b) the subskill definition and subskill-specific rubric descriptors. In the **zero-shot condition,** each essay was paired with a single target subskill. We asked the model to output both a proficiency label (0–4) and a concise justification aligned with the rubric. All 500 essays in the dataset were evaluated under this setting. In the **few-shot condition,** the prompt included the same instructions as above, with in-context examples for each proficiency level for the target subskill. We experimented with one, three, and five randomly selected in-context examples per proficiency level for each target subskill. To avoid data leakage, we excluded essays used as examples from the evaluation and tested the model on the remaining essays. For GPT-5, we used the default *reasoning effort* setting to balance performance and efficiency, and set the maximum output length to 3000 tokens to accommodate the model's reasoning traces and justification.

To complement our prompting experiments, we fine-tuned two open-source LLMs, Llama-3.1 8B Instruct, a decoder-only model with strong performance on several popular natural language processing benchmarks and ModernBERT-base, an encoder-only transformer, chosen for its lightweight design (149M parameters) and strong performance-size tradeoff on classification tasks. ModernBERT improves upon its predecessor BERT [13] with

training on much larger data and an 8k-token context window, making it well-suited for efficiently handling student essays.

For fine-tuning Llama, we constructed the input prompt by including the subskill name, definition and subskill-specific rubric descriptors corresponding to the five proficiency levels followed by the essay text to be classified. The output of the model is the proficiency level label text itself ('Not Applicable,' 'Below Emerging,' 'Emerging,' 'Expanding,' 'Exemplifying'). We fine-tuned the model using PEFT with LoRA adapters (rank=32, α=64, dropout=0.05), updating only adapter weights [26]. Training used a chat-style input-output format, optimized with AdamW for 3 epochs (batch size 4, gradient accumulation 4) with a 1,536-token sequence length. We selected the checkpoint with the best validation loss on a held-out validation set for inference.

For fine-tuning ModernBERT, like Llama, we construct the input prompt by including the subskill name, definition and subskill-specific rubric descriptors corresponding to the five proficiency levels. The output of the model is a single proficiency label (0–4). We added a lightweight classification head over the [CLS] representation and trained with AdamW and focal loss [36] to mitigate class imbalance for 6 epochs, using early stopping and a maximum input length of 1,536 tokens.

For Llama fine-tuning, in addition to outputting the label text, we experimented with a variant, where the model first outputs a short justification and then outputs the label text in order to elicit a chain-of-thought behavior [64] in the LLM to help in the reasoning process to generate the label [65]. Since our dataset does not contain gold justifications written by the human coders, we synthetically generate them by prompting OpenAI's GPT-4.1 to generate a sentence justifying the human label for a particular subskill for a given essay. We call this fine-tuning method "Llama (with justification)". In contrast, the default variant outputs only the proficiency label text (without generating a justification), which we refer to as "Llama (without justification)".

Additionally, to study the role of the subskill-specific rubric descriptors corresponding to the five proficiency levels in the input prompt, we consider two input prompt variants for both Llama and ModernBERT. In the with-rubric variant, the input prompt includes the subskill name, definition, and all rubric descriptors, along with the essay text. In the without-rubric variant, we remove the rubric descriptors and include only the subskill name and its definition, and the essay text. We refer to these variants as "Llama (with rubric)/ ModernBERT (with rubric)" and "Llama (without rubric)/ ModernBERT (without rubric)", respectively.

We evaluated two data-splitting regimes: 1) **Essay-based split**: essays divided into 70/10/20 percentages for the train/validation/test sets, respectively, with subskills constant, and results averaged across five random seeds. 2) **Subskill-based split**: one subskill held out entirely for testing; the other two used for training and validation with a 90/10 essay split. The first splitting setup is standard and evaluates LLMs' scoring ability when given on-task training data, i.e., human scored essays on each subskill. The second splitting setup tests generalization to new subskills, without using any human scores for previously unseen subskills.

3.4.2 Evaluation Metrics

To compare the performance of LLMs against human-annotated data, we evaluated performance across several metrics, each chosen to capture a different perspective on model behavior. **Accuracy** measures the proportion of exact matches between predicted and true labels. It offers an intuitive sense of overall correctness, but does not capture the severity of errors when predictions fall close to, but not exactly on, the target proficiency level. It also does not take class imbalance into consideration. Root Mean Squared Error (**RMSE**) treats rubric levels as points on an ordinal scale and penalizes deviations according to their distance. By squaring errors before averaging, larger deviations between the predicted score and the actual score are weighted more heavily, making RMSE suitable for ordinal classification tasks. **Macro F1** calculates the F1 (harmonic mean of precision and recall) score independently for each class and then averages across classes, giving equal importance to rare and frequent proficiency levels. This setup highlights whether a model can handle minority categories, such as 'Exemplifying,' as effectively as majority ones. **Weighted F1** also averages per-class F1 scores but weights them by class frequency, producing a summary that reflects the overall distribution of labels. This setup makes it more representative of performance in imbalanced datasets where some categories dominate. **Krippendorff's α** treats the model as a second annotator and quantifies agreement with human labels beyond chance. Since it is defined for ordinal scales, α accounts for the graded nature of rubric levels, providing a more nuanced measure of reliability than accuracy alone.

It is also important to note that there is not an expectation of near perfect performance in this case. There are no "correct" or "incorrect" ways to critically think, which is the case even for human coders. Therefore, it is not expected that an LLM would detect critical thinking subskills even better than humans. Rather, it is more likely that the LLM's would perform similarly to the detection of other complex cognitive constructs in the EDM field, such as frustration, engagement, and mind wandering [32, 42, 44]. To strengthen the trustworthiness of our results, we therefore evaluate our approach using multiple complementary metrics and, for the essay-based split, report averages across five random train/validation/test splits. This setup reduces reliance on any single metric or data split and supports interpreting the results as stable trends within this exploratory dataset.

4. RESULTS

4.1 Human Coding

The independent human coding resulted in 500 essays with proficiency level codes for each subskill. Table 3 shows the distribution of essays coded for each proficiency level across subskills.

For *Synthesizing Multiple Sources*, the most prominent proficiency level was 'Not Applicable,' which represented that the essays did not cite any sources, followed by 'Below Emerging,' which signifies that the essays only cited one source. Thus, for the majority of essays (91%), there was no opportunity to evaluate the degree to which students synthesized multiple sources, since multiple sources were not cited. For *Evaluating Evidence Strength*, 'Emerging' was the most prominent proficiency level (73%), which signifies that the essays presented evidence that was linked to specific conclusions, but did not evaluate the strength or relevance of the evidence.

For *Using Counterarguments* 'Not Applicable' was the most prominent proficiency level (46%) and suggests that the essays did not include any counterarguments. The next most prominent proficiency level was 'Below Emerging (23%) which included essays that only acknowledged vague counterarguments (e.g., others may disagree; 20%). 'Expanding' was the most prominent proficiency level for *Using Facts and Opinions* (34%), which applies to essays that used more facts than opinions to support the stated claims or arguments, followed by 'Below Emerging' (28%), which applies to essays that used more opinions than facts to support the stated

Table 3. Distribution of critical thinking proficiency levels by subskill

Skill	Not Applicable	Below Emerging	Emerging	Expanding	Exemplifying
Synthesizing Multiple Sources	287	168	19	18	8
Evaluating Evidence Strength	48	73	363	14	2
Using Counterarguments	231	113	62	77	17
Using Facts and Opinions	58	140	122	172	8
Drawing Conclusions	–	66	299	113	22
Using Logical Fallacies	15	121	132	230	2

claims or arguments. This finding may be explained by the variation in essay prompts and writing tasks as a review of the essays revealed that students were likely prompted in some to give their opinion, whereas in others they were prompted to leverage facts in provided source materials.

'Emerging' was the most prominent proficiency level for *Drawing Conclusions* (60%), followed by 'Expanding' (23%). This suggests that essays were typically able to draw a specific conclusion but were more likely to analyze simple, rather than complex, relationships. For *Using Logical Fallacies*, the most prominent proficiency level was 'Expanding' (46%) with 'Emerging' as the next most prominent (26%). Essays in the present sample tended to include evidence at an equal or greater amount than logical fallacies when generating arguments.

It is also noteworthy that across subskills the 'Exemplifying' proficiency level was extremely rare (<1% – 4%). This may be due to the essays being authored by students between grades 6 and 12 while the learning progression was developed specifically for high school students. The uneven distribution of proficiency levels, especially the rarity of 'Exemplifying' responses, also highlights a broader challenge for automated critical thinking assessment: models must be validated on additional datasets with different student populations, tasks, and proficiency distributions before claims can be generalized beyond the present setting.

4.2 LLM Scoring Results

4.2.1 Subskill Scoring

In the first experiment, we compared the performance of all three methods (zero-shot prompting, few-shot prompting, fine-tuning) and all three base LLMs (GPT-5, Llama, ModernBERT) on each subskill. We show the overall results in Table 4, averaged across test sets in five random seed splits of the dataset. Overall, fine-tuning Llama yields the strongest performance. The best variant is Llama (with rubric, without justification), which conditions on the subskill-specific rubric descriptors and predicts only the label. Importantly, Llama is the only model that crosses the $\alpha \geq .6$ threshold we originally adopted as sufficient reliability for human coders. This result indicates that fine-tuning a capable base LLM on our dataset is necessary to reach satisfactory performance, considering what is deemed acceptable for human interrater agreement.

Fine-tuning ModernBERT (with rubric) is not as effective as fine-tuning Llama: it underperforms Llama across all metrics with a notable gap of 4% and 6.5% in accuracy and Krippendorff's α respectively. For ModernBERT, rubric descriptors have limited impact: ModernBERT (without rubric) is only .8% lower in accuracy, and ModernBERT (with rubric) is only 1% lower in Krippendorff's α, suggesting the model relies primarily on the essay text during fine-tuning. We also found that ModernBERT is effective at capturing majority labels but struggles with less-frequent, minority labels, reflecting the challenges of fine-tuning on an imbalanced dataset even with the focal loss. These results highlight ModernBERT's limited model size (149M parameters compared to 8B parameters), making it less capable than Llama. Also, the decoder-only nature of Llama means that it generates the label text directly, instead of using a separate classification head for each subskill for ModernBERT. Therefore, it is easier for Llama to make the most use of textual rubric definitions for subskills.

Prompting GPT-5 with few-shot (with three in-context examples) yields better performance in comparison with zero-shot (~5.5%) in terms of Krippendorff's α with minimal differences across other metrics. This result shows that the in-context examples help in classifying the minority labels, improving the overall agreement with humans. Few-shot prompting with different numbers of in-context examples (one, three, and five) yields very similar results, with three in-context examples being slightly better (by 1% on accuracy and α) showing that increasing the number of in-context examples does not yield significant gains. The modest gains from few-shot prompting for GPT-5 also highlight its strong zero-shot ability: the model can adapt to the rubric with little additional context.

Comparing fine-tuning to prompting, we see that ModernBERT, despite being a smaller model, matches GPT-5 few-shot in terms of Krippendorff's α, while Llama fine-tuning outperforms it by 6%. Overall, fine-tuning smaller, open-source models outperforms prompting larger, proprietary start-of-the-art LLMs. These results highlight the importance of training with on-task data, since LLMs are not pre-trained on our specific task of critical thinking assessment. There are also additional benefits in cost and security: few-shot prompting has significantly higher cost (≈ $40 for scoring 500 essays with GPT-5 via the OpenAI API) and raises concerns about student data privacy.

Table 4. Scoring results on the essay-based split, averaged across test sets from five random seeds

Model	Method	Accuracy	RMSE	F1 (Macro)	F1 (Weighted)	Krippendorff's α
Llama 8B	Fine-Tune	.604 ± .012	.933 ± .043	.489 ± .022	.599 ± .016	.606 ± .032
ModernBERT	Fine-Tune	.563 ± .021	1.072 ± .066	.448 ± .019	.552 ± .025	.541 ± .044
GPT-5	Zero-Shot	.543 ± .013	1.094 ± .045	.443 ± .011	.541 ± .013	.487 ± .031
	Few-Shot	.532 ± .013	1.079 ± .031	.457 ± .023	.534 ± .015	.542 ± .016

Table 5. Results showing Llama fine-tuning variants using rubrics and justification

Rubric	Justification	Accuracy	RMSE	F1 (Macro)	F1 (Weighted)	Krippendorff's α
With Rubric	Without Justification	.604 ± .012	.933 ± .043	.489 ± .022	.599 ± .016	.606 ± .032
	With Justification	.573 ± .014	.974 ± .051	.455 ± .011	.562 ± .018	.588 ± .022
Without Rubric	Without Justification	.591 ± .015	.942 ± .036	.481 ± .025	.586 ± .019	.599 ± .034
	With Justification	.576 ± .004	.983 ± .035	.462 ± .011	.563 ± .006	.584 ± .011

4.2.2 Llama 3.1 8B Results

Table 5 shows results on different variants of Llama fine-tuning using rubrics and justifications. We see that including the subskill-specific rubric descriptors in the input prompt yields only slight improvement than not including it (by 1.3% in accuracy and .7% in Krippendorff's α for the Llama [without justification] variant). This result suggests that the model attends mostly to the essay text and the subskill name when making its classification, while the rubric information does not play a very significant role. This result can perhaps be explained by the data split, where scored examples of the same subskills are already seen during training, resulting in on-task training data. However, such rubrics may be useful when we generalize to unseen subskills, which we study in Section 4.2.3. We also see that not including the justification performs slightly better than including it in the output (by 3.1% in accuracy and 1.8% in Krippendorff's α for the Llama [with rubric] variant). This result suggests that the justifications might be noisy: they are not written by humans, which may add additional distracting information during the model's decision-making process.

Table 6 shows the results for our best-performing variant, Llama (with rubric, without justification) broken down across different subskills. We see that both the subskills in *Subskill 2 - Information Analysis* achieve the highest accuracy (around .78) compared to other subskills. We note that this result is likely due to the label distribution for both subskills being highly skewed, with the model mostly predicting the majority label. However, we do see a significant difference in the Krippendorff's α scores across subskills, with *Synthesizing Multiple Sources* having a Krippendorff's α of .74, showing the fine-tuned LLM as quite consistent with human judgement. On the contrary, *Evaluating Evidence Strength* has a low Krippendorff's α score of only .23. This difference is because the model always predicts the majority 'Emerging' label for *Evaluating Evidence Strength*, ignoring the 'Not Applicable' and 'Below Emerging' labels that are not seen much during training.

We also see that both subskills under *Subskill 3 - Argument Generation* achieve the lowest accuracy among the other subskills. This result can be explained by the balanced label distribution across the proficiency levels, where subtle differences in essays led to differences in labels, making it hard for LLMs to learn during training. Despite the lower accuracy, we see that *Using Facts and Opinions* achieves a Krippendorff's α of .55, which is close to the threshold we set for interrater agreement between human coders.

Finally, both subskills in *Subskill 4 - Logical Reasoning* have higher accuracy than *Subskill 3 - Argument Generation* but lower than those of *Subskill 2 - Information Analysis*. In particular, *Using Logical Fallacies* has an accuracy of only .50, compared to .61 for *Drawing Conclusions*. This result underscores the challenge in identifying different types of logical fallacies and differentiating them from the evidence, since the fallacies are often subtle and rarely labeled explicitly.

Taken together, these results suggest that fine-tuning Llama performs best in contexts where different proficiency levels are separable and well-represented. Performance significantly drops when different proficiency levels have minor differences or the labeled data is dominated by one level. Therefore, it is important to evaluate models with metrics beyond accuracy before considering potential classroom use.

4.2.3 Generalizing to Unseen Subskills

In this experiment, we evaluate whether a Llama model fine-tuned on labeled data on some subskills can generalize to other subskills that are previously unseen during training. Intuitively, since the definition of subskills and scoring rubrics defining each proficiency level are used as input, a trained model may acquire some knowledge on how to evaluate students' critical thinking as a whole, as well as gain knowledge on the operational definitions of the different proficiency levels. Therefore, the trained model may perform better in the cold-start setting, where human scores are not readily available for previously unseen subskills [64].

Table 7 shows results on the subskill-based data split where we see a clear performance drop compared to the essay-based split. Among the variants, Llama (with rubric, with justification) performs best in this setting, achieving Krippendorff's α around .42. However, the without-rubric variants, either with or without justification, achieve α values near zero. This result suggests that rubric descriptors are essential for cross-subskill generalization: Including the rubric provides the model with the context it needs to map an unseen subskill to proficiency level labels. This observation is in stark contrast to the essay-based split, where rubrics are not

Table 6. Subskill-wise results for the best Llama fine-tuning variant

Subskill	Accuracy	RMSE	F1 (Macro)	F1 (Weighted)	Krippendorff's α
Synthesizing Multiple Sources	.780 ± .037	.638 ± .108	.444 ± .061	.761 ± .040	.740 ± .063
Evaluating Evidence Strength	.768 ± .026	.707 ± .097	.303 ± .043	.711 ± .033	.234 ± .126
Using Counterarguments	.471 ± .042	1.408 ± .170	.236 ± .050	.416 ± .065	.315 ± .148

Table 7. Scoring results on the subskill-based split for Llama fine-tuning

Test Subskill	Accuracy	RMSE	F1 (Macro)	F1 (Weighted)	Krippendorff's α
Information Analysis	0.564	1.221	0.358	0.549	0.379
Argument Generation	0.389	1.357	0.293	0.356	0.418
Logical Reasoning	0.418	1.066	0.310	0.406	0.302
Overall	0.457	1.22	0.392	0.448	0.422

essential since the data split does not test generalizability to new subskills. For the rubric-based variants, adding justifications improves generalization: Llama (with rubric, with justification) outperforms Llama (with rubric, without justification) by 10% in accuracy and 6% in Krippendorff's α. This result differs from the essay-based split, where justifications provided little benefit. This observation suggests that generating justifications improves the model's reasoning by encouraging it to explain its label using rubric descriptors and evidence from the essay, which matters more when the target subskill is unseen during training.

Unfortunately, accuracy is low for some subskills (between 0.39 and 0.56), and Krippendorff's α falls below the reliability threshold we set for human annotators. These results suggest that models struggle to generalize when the target subskill is unseen during training. This observation underscores the importance of subskill-specific context for guiding classification. In particular, models rely on the rubric descriptors for each subskill; removing this information during training substantially degrades performance. These results suggest that effective scoring of new subskills will require subskill-specific labeled data.

Despite this difficulty in generalization, Information Analysis achieves the highest accuracy among the unseen subskills (.56). This result likely follows because the subskill has simpler classification boundaries and higher human interrater agreement, which makes the dominant label easier for the model to identify and predict consistently. Argument Generation achieves the highest Krippendorff's α (.41) but lower accuracy and higher RMSE. This result suggests that the model struggles to separate adjacent labels when the label distribution is more balanced, leading to confusion among intermediate levels. Logical Reasoning achieves the lowest Krippendorff's α (.30). This result likely reflects the complexity of the subskill, especially *Using Logical Fallacies*, which requires recognizing specific fallacy types and distinguishing them from evidence.

Taken together, these findings highlight the difficulty of generalizing across subskills without on-task training data. These findings also show some promise in generalization, with accuracy comparable to the essay-based split for a few subskills and fair Krippendorff's α scores across all subskills. Compared to GPT-5 zero-shot, which does not rely on training data for unseen subskills either since it is a prompting method, Llama fine-tuning performs slightly worse, by 8.6% overall in accuracy and 6.5% overall in Krippendorff's α. This drop in performance likely follows from subskill definitions and rubric criteria being sufficiently distinct, making extrapolation to other subskills difficult. Consequently, robust scoring of unseen subskills remains challenging and may require some subskill-specific supervision or LLM fine-tuning techniques that encode subskill-agnostic features.

Error Analysis

We conducted an error analysis of the best-performing method, fine-tuning Llama (with rubric, with justification) on *Using Logical Fallacies* (Subskill 4.2). The most common misclassifications are 'Expanding' classified as 'Emerging' (80), 'Emerging' classified as 'Below Emerging' (53), and 'Emerging' classified as 'Expanding' (46). We qualitatively examined three representative examples, one for each misclassification type.

The first example discusses electoral rules. The essay includes concrete evidence such as "The Electoral College consists of 538 electors… 270 electoral votes" and "Because of the winner-take-all system… the candidates don't spend much time." The model instead foregrounds fairness appeals such as "It's not fair Texas gets 38… New York only gets 3," and similar overgeneralizations as logical fallacies and minimizes evidence, leading it to predict 'Emerging' instead of 'Expanding'. The second example discusses classroom emotion-detection software. The essay includes technical evidence describing the Facial Action Coding System, such as "orbicularis makes crow's feet around your eyes" and "the mouth is stretched sideways using the zygomatic major and a different muscle called the risorius." The model instead emphasizes slippery-slope and speculative claims (e.g., "more and more ads… you might even get a virus," "watching you all day, everyday"), rather than "concrete evidence," leading it to predict 'Below Emerging' instead of 'Emerging'. The third example discusses Venus exploration. The essay includes research-like statements such as "far more extreme than anything humans encounter on Earth" and "97 percent carbon dioxide blankets Venus." The model instead gives disproportionate weight to the volume of citations while not recognizing contradictions in the essay's conclusion, leading it to predict 'Expanding' instead of 'Emerging'.

Taken together, these results indicate that most misclassifications occur between adjacent proficiency levels. These errors are most frequent around 'Emerging', which requires judging whether evidence and fallacies are roughly balanced. This judgment is difficult when fallacy detection depends on fine-grained distinctions. This result can likely be attributed to the inherent difficulty of identifying specific fallacy types (e.g., causation, false equivalence). These distinctions were provided to human coders but are not explicitly available to the model [39]. Our findings suggest that while LLMs can approximate human scoring, biased judgments of the balance between evidence and fallacies underscore the need for additional scaffolding or hybrid human-AI approaches for critical thinking assessment. Future work can test whether providing explicit fallacy definitions and labeled examples improves performance.

5. DISCUSSION AND CONCLUSION

In this paper, we developed and evaluated automated methods for assessing critical thinking subskills in student essays, attempting to address the pressing need for more reliable and robust measures of this dynamic and understudied form of higher-order reasoning. Our work used two complementary strategies: prompting proprietary LLMs under both zero-shot and few-shot conditions and fine-tuning open-source LLMs using human-labeled data. By doing so, we investigated the capability of these systems to detect critical

thinking subskills, such as constructing coherent arguments, systematically integrating evidence, and articulating meaningful counterarguments. Our aim is to provide the foundation for future EDM work on modeling critical thinking so that eventually such detectors can be used in educational environments.

Overall, these methods involve trade-offs between scoring quality and deployment constraints. Fine-tuning open-source models achieves the strongest performance, with Llama fine-tuning outperforming and ModernBERT matching, respectively, GPT-5 few-shot's performance in Krippendorff's α, despite their smaller size. This result highlights the value of on-task training data for critical thinking assessment. Prompting remains easier to deploy, but it can be more expensive at scale (≈ $40 for scoring 500 essays with GPT-5) and raises student data privacy concerns. At the same time, even for our best model, Llama 3.1 8B fine-tuning using rubrics and justifications, we noted inconsistent results across subskills. The model was especially challenged by subskills where there was a class imbalance and only subtle (rather than clearer) distinctions across proficiency levels. These challenges suggest that we need to incorporate data-level balancing (e.g., synthetic minority over-sampling) and cost-sensitive training into LLM fine-tuning for critical thinking assessment [59].

Our experiments with fine-tuning Llama show that adapting to unseen subskills remains difficult without on-task training data. Rubric descriptors are necessary for cross-subskill generalization, and generating justifications further improves performance. This result likely follows because justifications encourage the model to explain its label using rubric criteria and evidence from the essay, which helps it map an unseen subskill to the proficiency levels more consistently. However, reliability remains below our target threshold. Performance also drops relative to settings where the target subskill is seen during training. This finding suggests that robust scoring of new subskills will require some subskill-specific human supervision, such as a small set of labeled essays or curated in-context examples. Future work may also investigate meta-prompting methods to automatically generate rubrics given description of previously unseen skills. Deploying automated critical thinking assessment in practice will require either subskill-specific labeled data or mechanisms to encode transferable traits across related subskills.

We acknowledge that selecting 0.6 as a threshold for reliability (compared to typical 0.8) affects the interpretation and use of our findings. However, this decision was intentional given the exploratory nature of this work and our long-term goal of developing a model for critical thinking that can be used in AI tools. A limitation of this initial work is that we evaluated a small set of models and prompting settings, even as the space of LLMs and prompting strategies for AES and related tasks continues to expand. It is therefore possible that other proprietary models (o3, o4-mini-high, Opus 4.6), alternative prompting strategies, or different open-weight models (Qwen [3], or DeepSeek [12]) would yield stronger performance for critical thinking assessment. The bottom line is that our experiments provide evidence that open-weight LLMs, after some training, can be competitive in this setting. The rapid pace of LLM development remains a challenge for interpreting and comparing results over time. Similarly, a broader range of critical thinking skills and contexts for its application will need to be studied before we can confidently draw conclusions about the usefulness of LLMs for measuring critical thinking as a whole.

Nonetheless, these preliminary results demonstrate that there is potential for LLMs to assess a range of critical thinking skills efficiently, rapidly, and cost-effectively, in the context of authentic student work. LLMs can potentially become a tool to support expanded and more extensive research on critical thinking, the relationship between its components, the processes involving its development, and its relationships to other forms of complex student cognition. This work lays the groundwork for AI models that can give teachers meaningful insights into how students' critical thinking is developing and that can be embedded in adaptive learning systems to help cultivate the skills humans will need most as they navigate an era of AI-generated content, disinformation, and increasingly complex global challenges.

ABSTRACT

We introduce the Unified Neural Variational Measurement of Proficiency (UNVaMP) architecture, a knowledge tracing method that integrates observed student-item interactions with internal memory to produce evolving latent representations of student knowledge. These representations support accurate predictions of future responses while enabling explicit control over the smoothness of estimated learning trajectories. UNVaMP can be configured as either a purely neural model or a hybrid model that predicts responses through an interpretable measurement function over the latent space. We show that a pure neural configuration (UNVaMP-MLP) achieves the strongest predictive performance among compared models on three out of four datasets. Meanwhile, a hybrid configuration (UNVaMP-MIRT, using a 1PL MIRT measurement function) lags only slightly behind UNVaMP-MLP, indicating that the predictive cost of interpretability is modest.

Beyond predictive accuracy, UNVaMP provides the following: a principled mechanism for controlling volatility when estimating student latent variables, quantification of uncertainty over student knowledge state estimates, and flexible input specification that supports heterogeneous student-item interaction features. In addition, the hybrid UNVaMP-MIRT configuration generates interpretable moment-in-time student knowledge state estimates. Using an experimental dataset, we show that auxiliary inputs induce structured changes in the predictive behavior of UNVaMP-MIRT, consistent with sensitivity to underlying structure beyond response correctness. Furthermore, through a simulation study, we show that UNVaMP yields well-behaved knowledge state estimates under controlled measurement conditions. In total, these results indicate that UNVaMP is both practically useful for real-world education systems and capable of recovering meaningful underlying structure from student-item interactions.

Knowledge Tracing, Deep Learning, Latent Variables, Interpretability, Uncertainty Quantification

1. INTRODUCTION

Building models of student learning often involves balancing competing needs for rigorous student knowledge estimation and flexible model fitting over large, sparse, and noisy datasets, while recognizing that student knowledge evolves with each interaction. In contrast, classical measurement models are typically designed for tightly controlled test environments (e.g., standardized tests) and impose strict assumptions about student latent knowledge structures. Knowledge tracing (KT) models seek to incorporate sequential (or temporal) information about student-item interactions and fall into two broad categories: those rooted in classical statistical frameworks [13, 33, 36], and those built upon modern deep learning methods [10, 27, 37]. Classical approaches often preserve much of the framing of traditional measurement models but relax certain constraints to capture learning dynamics and may support less controlled settings. Modern deep learning approaches to KT typically relax both statistical and latent knowledge assumptions in pursuit of flexibility and predictive power, although hybrid and theory-informed methods are increasingly prevalent in the literature.

In the remainder of this section, we briefly summarize the measurement and KT paradigms, followed by a discussion of existing KT methods, along with their strengths and limitations, then distill from this analysis a set of architectural desiderata outlining desirable properties for modern KT architecture designs. The UNVaMP architecture is then described in detail in Section 2. We then describe our datasets and experiments in Section 3, followed by a presentation of our results in Section 4. Finally, we summarize our findings and discuss limitations and future work in Section 5.

1.1 Classical Measurement Models

In classical measurement, models are built around an underlying construct of interest, typically represented by one or more latent variables that are assumed to be static within the measurement window [4]. In such models, student and item parameters are estimated directly, often via maximum likelihood, the expectation-maximization (EM) algorithm, or related variational approaches, rather than through amortized inference [20]. Although there are limitations with

these models in terms of predictive performance and flexibility, they are popular due to their interpretability, well-understood statistical properties, and mature implementations. Two very popular classical frameworks are Item Response Theory (IRT) and Cognitive Diagnostic Modeling (CDM). We briefly discuss IRT below, but point readers towards other materials discussing the properties and usage of CDMs [41, 44].

1.1.1 Item Response Theory

IRT is a classical measurement framework in which observed student-item interactions are modeled as a probabilistic function of latent student proficiency and item characteristics [20]. Multidimensional IRT (MIRT) extends this framework by defining latent proficiency as a vector, where each dimension represents a latent skill [39]. For instance, the two-parameter logistic (2PL) MIRT model is formulated as

$$P\left[Y_{i,j} = 1 \mid \theta_i, a_j, d_j\right] = \frac{1}{1 + \exp\{-(a_j^\top \theta_i + d_j)\}},$$

where $Y_{i,j} \in \{0, 1\}$ denotes an incorrect or correct student response to item j, θ_i is the latent proficiency vector for student i, a_j is the vector of item *discrimination* (or *loading*) parameters, and d_j is a scalar item intercept related to that item's *difficulty*. The vectors θ_i and a_j have one dimension per latent skill. The one-parameter logistic (1PL) MIRT model, also known as the multidimensional Rasch model, is a restricted case of 2PL MIRT where the dimensions of a_j have fixed values (typically 0 or 1).

1.2 Knowledge Tracing

Knowledge tracing is a broad category of methods that, unlike classical measurement models, treat student knowledge as evolving throughout a sequence of student-item interactions [42]. We group KT approaches into two broad categories: those grounded in classical measurement philosophies or statistical frameworks, and those built on modern deep learning methods. In our discussion of deep learning knowledge tracing (DLKT), we examine approaches that focus primarily on prediction, as well as hybrid methods that incorporate elements of classical measurement.

1.2.1 Classical and Statistical KT Methods

Classical and statistical KT methods typically model student knowledge directly and may utilize a longitudinal or dynamic adaptation of a classical measurement model. Popular families include Bayesian Knowledge Tracing (BKT) [13, 2], Elo [19, 36], and various dynamic IRT and CDM models [45, 53, 49, 24, 22, 7, 52]. Many variants exist, but all primarily consist of estimating student and item parameters given a sequence of student-item interactions.

Within classical KT, another well-studied and typically high-performing family of models is Logistic Knowledge Tracing (LKT) [32]. LKT is a framework that attempts to unify the many previous KT models that use logistic regression as their core predictive model. These prior models typically use hand-engineered features that could in principle be used together but were not (e.g., AFM [5], PFA [31], variants of PFA [18], R-PFA [14], spacing models like PPE [46, 47], and other features inspired by cognitive psychology [30]). However, selecting among these candidate features is challenging, so feature selection using lasso regression was included in the framework. The lasso regression approach was recently found to outperform several popular deep learning approaches on four benchmark datasets [35].

Despite their conceptual clarity, classical methods often suffer from several major shortcomings. First, longitudinal variants of IRT and CDM often require re-fitting student (and possibly item) parameters to obtain updated estimates given new observations [49]. Other variants of these IRT and CDM methods, along with models like Elo [36], support using updating rules for real-time parameter re-estimation, but these require analytical derivations or heuristics that limit model expressiveness, and these methods may still struggle to scale with larger datasets [25]. In addition, when many skills are present (e.g., dozens or hundreds), especially in large datasets, CDM and IRT methods may fail to converge without imposing significant assumptions or structural simplifications. Finally, classical approaches typically do not flexibly support auxiliary inputs beyond minimal predictors (e.g., sequential binary responses). Those that do, such as explanatory IRT or LKT models, utilize manually engineered features and require strong assumptions about functional relationships between inputs and outputs [56]. This manual approach can become cumbersome as new data sources become readily available (e.g., open-ended text responses), requiring significant resources to develop new features or adapt existing ones. This limitation extends to features intended to act as latent variables representing student knowledge, such as those intended to behave similarly to Elo parameters [34], since their interpretation will be confounded by the inclusion of new auxiliary inputs.

1.2.2 DLKT Methods

In response to the limitations of classical methods, numerous DLKT architectures have emerged over the past decade, ranging from those focused primarily on obtaining maximum predictive accuracy, to hybrid approaches that incorporate interpretable representations of student knowledge, item properties, or learning dynamics.

Prediction-focused DLKT architectures generally forgo interpretable student or item representations, limiting their scope to next-response prediction in sequences of student-item interactions. The first major example was DKT [37], a recurrent architecture focused exclusively on prediction. Following its introduction, numerous DLKT models have been proposed, many achieving state-of-the-art performance at the time of publication. Prominent examples include SAKT [27], AKT [16], and SAINT [10]. Within the prediction-focused DLKT paradigm, various extensions have been explored, such as incorporating uncertainty estimation [8, 12, 40]. DLKT models can exhibit volatility and unintuitive behavior in student learning dynamics [23, 59, 54, 62, 60]. Proposed remedies have included penalization of output-space inconsistency [59], attention mechanisms [54], and contrastive training procedures [60]. Despite these advances, such models remain largely uninterpretable and focused on prediction.

To address these interpretability limitations, several hybrid architectures incorporating elements of classical measurement, such as IRT- or CDM-based outputs, have been pro-

posed [51, 55, 57, 43]. Many early hybrid methods assumed static data generation and did not model learning dynamics. More recently, dynamic hybrid architectures suitable for KT have emerged, incorporating interpretability constraints such as IRT-style response functions [58, 6, 63], CDM-inspired interaction functions [50], or structured dynamics [28, 48]. However, to our knowledge, methods that introduce interpretability into the prediction mechanism do not tend to incorporate accompanying dynamics regularization [58, 6], while methods that impose structure on dynamics do not produce interpretable knowledge states [28, 48], and uncertainty representation is often left unaddressed.

1.3 Architecture Desiderata

Although knowledge tracing models are often judged primarily by predictive accuracy, prior work has argued that additional attributes are critical for practical usability [38]. We propose a set of architectural desiderata to guide DLKT architecture design and address common challenges with existing approaches. While many models satisfy subsets of these desiderata, we are unaware of any that explicitly address each of them.

1.3.1 Regularization of Dynamics

The volatility issues that have been observed in the DLKT paradigm may hamper their usability in many real-world contexts. In deployed systems, models with poorly constrained dynamics can yield unstable proficiency estimates that undermine reliability and interpretability. Accordingly, DLKT methods should incorporate explicit regularization mechanisms that promote smooth, stable trajectories of the inferred student knowledge states.

1.3.2 Interpretable Knowledge States

Although many DLKT architectures exist, few output interpretable knowledge states. Full transparency into all internal mechanisms (e.g., dynamics and response prediction) is ideal but impractical in DLKT without imposing constraints that undermine the benefits of deep learning. Instead, we suggest that moment-in-time summaries of student knowledge are sufficient for many practical use cases, provided the underlying dynamics are well-regularized, even if those dynamics are not themselves interpretable. To date, many hybrid methods either provide only partial knowledge state interpretability, or are too constrained to fully leverage DLKT's expressiveness. Thus, a model that allows users to specify an interpretable latent knowledge representation while retaining flexibility in modeling student learning dynamics would be highly useful.

1.3.3 Uncertainty Quantification

A common challenge for DLKT models is the absence of distributional and structural assumptions that underpin classical uncertainty quantification, making it difficult to define appropriate standards for uncertainty updating and calibration in practice. Nevertheless, a DLKT model should provide an internally consistent representation of uncertainty that reflects changes in its confidence as evidence accumulates. Even without statistical guarantees, such uncertainty estimates have practical utility, such as revealing diminishing returns as data accrue, informing when inference outputs should be surfaced, and enabling diagnostic analyses related to external signals such as proportion correct or recency.

1.3.4 Flexibility of Inputs

A major benefit of deep learning is that it relaxes two onerous requirements of classical modeling: pre-specifying functional relationships between inputs and outputs, and hand-engineering features to increase model capacity. Accordingly, a DLKT model should be capable of incorporating arbitrary sets of inputs, provided they do not introduce information leakage with respect to the response. While classical methods can, in principle, be expanded to accommodate additional inputs (e.g., via additional coefficients), this flexibility is largely nominal in practice. Such approaches scale poorly to large feature spaces, and still require pre-specified functional forms (e.g., linear effects or interaction terms).

2. THE UNVAMP ARCHITECTURE

We introduce the Unified Neural Variational Measurement of Proficiency (UNVaMP) architecture. Inspired by dynamic deep learning architectures that encode sequential inputs as latent distributions [12, 17], UNVaMP combines a memory model and an inference model (encoder) to produce moment-in-time latent knowledge state distributions, which are passed through a response model to predict student-item interaction outcomes. The response model thus serves as a modular decoder that determines how latent distributions map to predictions, and whether those latent distributions carry interpretable meaning. When configured with a neural decoder (UNVaMP-MLP), the latent space has no prescribed interpretation; when configured with a 1PL MIRT measurement function (UNVaMP-MIRT), the latent dimensions are directly interpretable as per-skill proficiency estimates, and item embeddings correspond to skill loadings and intercepts.

In UNVaMP, latent dynamics are regularized via a Kullback-Leibler divergence penalty between temporally adjacent distributions. When the response model is an interpretable measurement function, UNVaMP yields knowledge state estimates with prescribed meaning. Because inputs and memory are encoded as latent distributions, uncertainty representations are available through distributional parameters. All configurations support arbitrary auxiliary inputs. Use of the term "variational" refers to regularization of latent dynamics via a distributional divergence penalty, not variational Bayesian inference. Fig. 1 provides a full diagram of the architecture.

2.1 Inference Model and Memory Model

For a given student, the *inference model* (or encoder) f_z uses extracted features and hidden states—representing the model's internal memory—to output the mean and variance of a Gaussian distribution over the student's latent proficiency at a given time point. The hidden states are the outputs of the *memory model* f_h, a recurrent neural network (RNN) that uses extracted features to build an internal hidden memory representation of the student; see Fig. 1(a)–(b).

For student i with a sequence of student-item interactions at time points $t = 1, 2, ..., T_i$, the following inputs are available

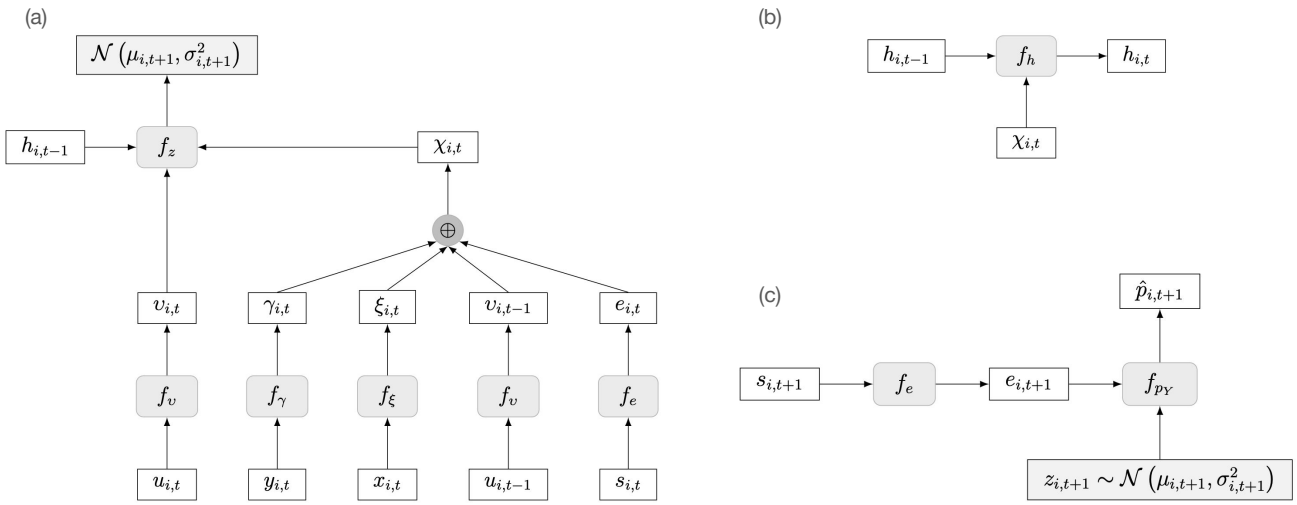

Figure 1: Overview of the UNVaMP architecture. Panel **(a)** shows the *inference model*, which combines internal memory about student i with extracted features from their most recent interaction to obtain an estimated latent knowledge distribution. Panel **(b)** shows the *memory model*, which combines the previous internal memory about student i with extracted features from their most recent interaction to obtain an updated internal memory. Panel **(c)** shows the *response model*, which receives latent variable samples from the knowledge state distribution for student i and generates predicted responses to items.

for each t:

$$(y_{i,t}, s_{i,t}, x_{i,t}, u_{i,t}),$$

where $y_{i,t}$ denotes the observed response data (e.g., correct/incorrect) and $s_{i,t}$ is an identifier (typically an integer index) for the item the student interacted with. The variable $x_{i,t}$ reflects any auxiliary data pertaining to the student-item interaction (e.g., item or skill metadata), and $u_{i,t}$ represents pre-response data that are measured before the next response $y_{i,t+1}$ is observed, such as the time-gap between t and $t+1$. The $x_{i,t}$ and $u_{i,t}$ inputs are optional, and can be flexibly specified, so long as they do not leak information about the response at $t+1$. In this study, predictions target only the binary correct/incorrect score at $t+1$.

During the forward pass, the inputs are sent through *feature extractors* f_γ, f_ξ, f_υ, and an *item embedder* f_e to obtain:

$$\gamma_{i,t} = f_\gamma(y_{i,t}), \quad \xi_{i,t} = f_\xi(x_{i,t})$$
$$\upsilon_{i,t} = f_\upsilon(u_{i,t}), \quad e_{i,t} = f_e(s_{i,t}),$$

Where $\gamma_{i,t},\ \xi_{i,t},\ \upsilon_{i,t},\ e_{i,t} \in \mathbb{R}^d$ and d is a specified (or tuned) embedding/encoding dimensionality. The representations $\gamma_{i,t}$, $\xi_{i,t}$, and $e_{i,t}$, along with $\upsilon_{i,t-1}$ (the extracted pre-response features from $t-1$), are then concatenated to obtain:

$$\chi_{i,t} = [\gamma_{i,t}, \xi_{i,t}, \upsilon_{i,t-1}, e_{i,t}].$$

The representation $\chi_{i,t}$ describes the full set of data available immediately after observing $y_{i,t}$. The hidden state $h_{i,t-1}$ is obtained from the memory model f_h using $\chi_{i,t-1}$ and $h_{i,t-2}$:

$$h_{i,t-1} = f_h(\chi_{i,t-1}, h_{i,t-2}),$$

where $h_{i,t-1}$ reflects UNVaMP's internal memory about student i, prior to observation t.

Then, $\chi_{i,t}$, $\upsilon_{i,t}$, and $h_{i,t-1}$ are passed to the inference model f_z, which outputs a Gaussian distribution over student latent variable $z_{i,t+1}$:

$$\mathcal{N}(\mu_{i,t+1}, \sigma^2_{i,t+1}) = f_z\left(\chi_{i,t}, \upsilon_{i,t}, h_{i,t-1}\right),$$

where $\mu_{i,t+1}$ represents the expected value of $z_{i,t+1}$, and $\sigma^2_{i,t+1}$, a vector representing the diagonal of a covariance matrix, reflects the model's uncertainty about $z_{i,t+1}$. Here, we have that $\mu_{i,t+1},\ \sigma^2_{i,t+1},\ z_{i,t+1} \in \mathbb{R}^k$, where k is the latent dimensionality. The $t+1$ subscripts denote that these values represent the model's belief about what the student's knowledge state will be at the time of response $t+1$. During training, $z_{i,t+1}$ is sampled from $\mathcal{N}(\mu_{i,t+1}, \sigma^2_{i,t+1})$ in the forward pass, while during inference, it is given by point estimate $z_{i,t+1} = \mu_{i,t+1}$.

We conclude our discussion of the inference model f_z and memory model f_h by noting several design choices. First, features $\chi_{i,t}$ are passed directly to f_z, rather than via f_h. This restricts the role of f_h to that of a memory mechanism only, preventing it from being the conduit of new information at time point t. Second, the latent variable $z_{i,t+1}$ is never ingested by f_h, imposing a separation between the internal representations learned by f_h and the point-in-time summaries given by f_z. In doing so, the internal expressiveness of the memory and inference models is left unconstrained by the latent distributions they produce. This separation has the added computational benefit of allowing the memory model to operate independently of the inference model's outputs during the forward pass, permitting the use of optimized sequence processing without the bottleneck of sequentially ingesting sampled latent variables.

2.2 Response Model

The *response model* f_Y, shown in Fig. 1(c), maps student latent knowledge states, along with item embeddings, to predicted response probabilities.

Once the student latent variable $z_{i,t+1}$ is obtained from f_z

and the next-item embedding $e_{i,t+1}$ is obtained from the embedder f_e via $e_{i,t+1} = f_e(s_{i,t+1})$, these values are passed into f_Y to obtain:

$$\hat{p}_{i,t+1} = f_Y(z_{i,t+1}, e_{i,t+1}),$$

where $\hat{p}_{i,t+1}$ is the scalar predicted probability that student i will respond correctly to item $s_{i,t+1}$ at time point $t+1$, conditioned on the latent variable $z_{i,t+1}$ and the item embedding $e_{i,t+1}$. The items $s_{i,t+1}$ are known during training, and can be chosen arbitrarily during inference.

When f_Y is a known measurement function, it determines the interpretation of the latent distribution. For the 1PL MIRT configuration used in this study, the item embedder f_e outputs interpretable embeddings

$$e_{i,t+1} = \left(a_{s_{i,t+1}}, d_{s_{i,t+1}}\right),$$

so that:

$$\hat{p}_{i,t+1} = \frac{1}{1 + \exp\{-(a_{s_{i,t+1}}^{\top} z_{i,t+1} + d_{s_{i,t+1}})\}}.$$

Here, the "embedding" is a tuple containing $a_{s_{i,t+1}}$ and $d_{s_{i,t+1}}$, which represent the loadings and intercept for item $s_{i,t+1}$, where $d_{s_{i,t+1}}$ can either be learned during fitting or supplied as data. In this study, we utilized fixed binary skill tags as loadings, giving $a_{s_{i,t+1}} \in \{0,1\}^k$, and learned $d_{s_{i,t+1}}$ during fitting. A key constraint of our implementation is that f_Y takes only student latent variables and item embeddings as input, following the standard practice in most measurement functions, allowing UNVaMP to support interpretable response model configurations.

2.3 Training Objective

The UNVaMP training objective takes the form:

$$\mathcal{L} = \mathcal{L}_{\text{pred}} + \beta D_{\text{KL}},$$

where $\mathcal{L}_{\text{pred}}$ denotes the prediction loss (binary cross-entropy in our case), D_{KL} denotes the Kullback-Leibler (KL) divergence [3], and β is a regularization coefficient. Because UNVaMP represents student knowledge as latent probability distributions, we require a mechanism to regularize how these distributions evolve over time. As such, we compute D_{KL} over temporally adjacent latent distributions:

$$D_{\text{KL}}\left(\mathcal{N}(\mu_{i,t+1}, \sigma_{i,t+1}^2) \,\|\, \mathcal{N}(\mu_{i,t}, \sigma_{i,t}^2)\right),$$

constraining how much the new knowledge state distribution $\mathcal{N}(\mu_{i,t+1}, \sigma_{i,t+1}^2)$ diverges from the previous distribution $\mathcal{N}(\mu_{i,t}, \sigma_{i,t}^2)$. This results in smoother estimated student learning dynamics and tempers the local variation of f_z and f_h (indirectly), with β regulating the level of imposed smoothness. Note that $\mathcal{L}_{\text{pred}}$ and D_{KL} are scalar aggregated values. To prevent latent dimensionality from inflating or deflating the KL divergence, we perform mean-reduction rather than sum-reduction of these quantities. This is especially important in the case where the latent space is tied to an interpretable measurement function, since the dimensionality of the latent space should not artificially inflate or deflate the KL divergence penalty.

While UNVaMP is inspired by the dynamic VAE literature [12, 17], it does not perform variational Bayesian inference. Unlike standard VAE formulations, where the KL divergence is computed between an approximate posterior and a prior, UNVaMP uses the KL divergence solely as a regularization mechanism to impose smoothness on the latent knowledge distribution trajectories.

2.4 Alignment with Architecture Desiderata

UNVaMP was designed to address the DLKT architecture desiderata outlined in Section 1.3. Specifically, the β term in UNVaMP's training objective provides a mechanism for regularizing the estimated latent dynamics, allowing users to control the trade-off between smoothness and predictive performance. UNVaMP also supports using known measurement functions (e.g., MIRT) as the response model, yielding interpretable moment-in-time knowledge state estimates and item parameters (intercepts and loadings) when so configured. In addition, UNVaMP generates latent distributions representing student knowledge states, enabling representations of internal uncertainty. Although these estimates do not provide formal coverage guarantees, they capture relative model confidence in the latent estimates. Finally, UNVaMP accommodates arbitrary response, auxiliary, and pre-response inputs. In this study, the full set of desiderata is realized under the UNVaMP-MIRT configuration with $\beta > 0$, while UNVaMP-MLP retains the flexibility, uncertainty, and regularization properties without imposing interpretability constraints on the latent space.

3. METHODS

This section describes the models, datasets, and experimental procedures employed in this study. First, we introduce the UNVaMP configurations and baseline model architectures utilized in our experiments. Next, we discuss the public, internal, and simulated datasets on which our experiments were conducted. We then conclude with a description of the experimental setup and evaluation protocols.

3.1 Models

UNVaMP was benchmarked against a representative set of classical, hybrid, and deep learning KT models. These baselines were chosen to provide well-known comparison points with different approaches to dynamics, interpretability, and model capacity. Below, we describe the models and configurations used in our experiments.

3.1.1 UNVaMP

For benchmarking, we evaluated two configurations of UNVaMP that differ only in the specification of the response model. The first, UNVaMP-MLP, uses a neural network decoder as the response model. The second, UNVaMP-MIRT, is a hybrid configuration in which the response model is a 1PL MIRT measurement function. Here, the item embedder consumes pre-specified binary skill tags for each item, which are used as fixed loading parameters, while item intercepts are learned as one-dimensional embeddings. For the memory model, we used a Gated Recurrent Unit (GRU) RNN [9].

3.1.2 BKT

Bayesian Knowledge Tracing (BKT) is a Hidden Markov Model-based knowledge tracing method that uses response history to estimate future proficiency and correctness. The model uses four key parameters: initial knowledge probability, learning rate, guess rate (correct answer despite not

Table 1: Dataset summaries.

Dataset	Obs.	Students	Items	Skills
ASSISTments	172,200	1,561	548	78
EdNet	2,085,026	18,326	9,198	187
Cloze	45,115	478	144	36
Amplify	7,583,010	107,169	2,346	43

knowing), and slip rate (incorrect answer despite knowing). We used the BKT implementation in the pyBKT package [1].

3.1.3 Deep-IRT

Deep-IRT is an extension of the Dynamic Key-Value Memory Network (DKVMN) architecture that predicts the probability of a correct response using a Rasch-style measurement function [58]. Like DKVMN, Deep-IRT employs a static key memory to compute attention weights over knowledge components, and a dynamic value memory that is updated using embeddings of student-item interactions [61]. Deep-IRT then estimates latent student traits and item difficulties that are combined using the Rasch measurement function to predict probability of correctness. For our experiments, we used the Deep-IRT implementation provided by the pyKT Toolkit package [26].

3.1.4 SAINT

SAINT is a DLKT method based on the influential transformer architecture [10]. In SAINT, a multi-head attention mechanism is used within an encoder-decoder architecture, where the encoder models the exercise sequence and the decoder attends to prior responses and the encoded exercises to predict response correctness. For our experiments, we used the SAINT implementation provided by the pyKT toolkit, with minor implementation-level modifications that do not alter the model architecture. Specifically, we used PyTorch's built-in transformer encoder and decoder modules (rather than from-scratch implementations) and employed a shared positional embedding layer in the encoder and decoder blocks.

3.1.5 LKT

We used the lasso regression implementation in the LKT package in R [33] to create features and train models, in which a penalty term is applied to the objective function and may reduce coefficients to zero. This approach was implemented to avoid challenges with feature selection [35].

3.2 Data

The data used in this study fall into three categories: public, internal, and simulated. Public and internal datasets were used for evaluating UNVaMP against existing knowledge tracing models on known benchmarks and in a real-world context, while the simulated data were used to assess UNVaMP's latent structure recovery capacity and inference behavior under controlled conditions.

3.2.1 Public Datasets

Three public datasets were selected for this study: ASSISTments, EdNet, and Cloze. Dataset-specific preprocessing is described below. In addition, iterative threshold filtering was applied to retain only students with responses to at least ten unique items and items with responses from at least one hundred unique students. For multi-skill items, observed per-item skill combinations were used as skill tags for all models except UNVaMP-MIRT, where latent dimensions corresponded to atomic skills. Table 1 summarizes each dataset. Each dataset was divided into a 60/20/20 train/validation/test split unless otherwise noted.

ASSISTments. The ASSISTments dataset contains student-item interactions from the ASSISTments online math tutoring platform, which provides immediate feedback and optional scaffolds and hints [21]. In this study, we used the ASSISTments 2017 dataset released for the 2017 ASSISTments Longitudinal Data Mining Competition [29], a longitudinal dataset with nearly one million student actions from over 1,700 students spanning secondary through tertiary education. To better reflect non-intervention assessment moments, we retained only single-skill items (dropping untagged and multi-skill items) and excluded responses involving scaffolds or hints, as well as responses on student-item pairs where the initial response used assistance.

EdNet. The EdNet dataset contains student-item interaction data from Santa, an intelligent tutoring system used by South Korean students to prepare for the Test of English for International Communication (TOEIC) [11]. EdNet contains data from over 750,000 students and is organized into four datasets with varying levels of behavioral detail. We randomly sampled 20,000 students from the KT1 subset prior to threshold filtering. We then removed duplicate interactions within sessions and interactions missing responses, imposed a cap of 500 interactions per student (approximately three standard deviations above the in-dataset mean) to reduce computational demands during model fitting.

Cloze. The Statistics Cloze dataset (referred to as "Cloze" in this study) was obtained from Memphis Datashop via the LKT R package [33]. The data consist of responses from Amazon Mechanical Turk participants who studied statistical concepts through short readings and completed cloze-style exercises, with each sentence associated with one of 36 skills. Sentence presentation frequency and temporal spacing (narrow, medium, wide) were experimentally manipulated, with post-practice tests administered after delays of 2 minutes, 1 day, or 3 days. We removed observations without a correctness score. Due to the small dataset size, we used a 50/25/25 train/validation/test split with stratified sampling to maintain balance across experimental conditions.

3.2.2 Internal Dataset

Amplify Dataset. The Amplify dataset consists of student-item interactions from a K-8 mathematics curriculum delivered via an online platform, including summative pre-unit, mid-unit, and end-of-unit assessments, as well as formative in-lesson assessments. Though responses were primarily

auto-scored as correct or incorrect, when available, teacher re-scores were used in place of auto-scores. In this dataset, questions are tagged to a hierarchical proficiency map of math skills, and for this study, skill tags were drawn from the highest-level nodes. Only non-empty responses were retained and untagged items were excluded. The dataset was de-identified, with all personally identifiable information removed prior to use.

3.2.3 Simulated Dataset

We simulated student response data from a 1PL MIRT model. First, a global skill-skill covariance matrix Σ was constructed with unit variances on the diagonal and off-diagonal entries drawn uniformly from the range $[0.2, 0.6]$, with Σ constrained to be positive semi-definite. Next, a scalar overall proficiency x_i was drawn from a standard normal distribution for each student. Per-student θ_i vectors were then sampled from $\mathcal{N}(x_i \cdot \mathbf{1}, \Sigma)$. Item difficulties b_j were sampled from a standard normal distribution, with equal numbers of single-skill items per skill. Responses were generated by computing item intercepts $d_j = -b_j$ and applying the MIRT measurement function, then sampling Bernoulli outcomes. All students interacted with all items, and within-student item interaction order was randomized such that more difficult items tended to be seen later. Each simulated dataset contained 5 skills, 50 items per skill, and 10,000 students.

3.3 Experiments

3.3.1 Model Benchmarking

For the model benchmarking experiments, we fit all models to the public and internal datasets, then characterized predictive performance and smoothness.

Prior to benchmarking, hyperparameters for all deep learning models were tuned using Bayesian optimization. Across models, tuning included the learning rate, embedding dimensionality, and dropout probability. For UNVaMP, additional hyperparameters included the hidden state dimensionality and the number of hidden layers in the RNN and feature extractors; for UNVaMP-MLP, the number of hidden decoder layers was also tuned. For Deep-IRT, tuning included the batch size, the number of rows in the key and value memory matrices (constrained to be equal), and the maximum input sequence length. The latter was introduced to circumvent VRAM limitations, such that longer input sequences were split into subsequences and treated as additional samples during training. For SAINT, tuning included the batch size, the number of encoder and decoder layers (constrained to be equal), the number of attention heads, and the maximum input sequence length (used similarly to Deep-IRT). All DLKT models were trained using Adam-based optimizers with default settings, with UNVaMP trained using AdamW. For LKT, we included the same features as described in the original LKT-lasso paper, with the addition of power-law decay and PPE [35]. Hyperparameters for PPE were estimated via maximum likelihood on the training set. Other features with hyper-parameters were generated on a 0-1 grid (step=0.1).

Because LKT and UNVaMP allow flexible specification of input features, we evaluated two versions of each model. The minimal versions were trained using the same inputs as the other benchmark models: item ID, skill ID, sequence position, and response correctness (and features derived from these inputs). The (aux) versions included all minimal inputs plus available auxiliary inputs, which varied by dataset (e.g., problem type, bundle ID). All datasets provided submission timestamps, from which recency features (e.g., time since previous submission) were computed.

Benchmark fits of UNVaMP-MLP and UNVaMP-MIRT were conducted using $\beta \in \{0, 10^{-3}\}$ to reflect peak predictive performance. To examine the trade-off between predictive performance and regularization, we compared UNVaMP-MIRT (aux) fits across $\beta \in \{0, 10^{-3}, 10^{-2}, 10^{-1}\}$ for each dataset. To quantify the smoothing effect of β on the latent dynamics, we report what we call the *average latent total variation* (ALTV). ALTV can be viewed as a normalized, fixed-sample analogue of *total variation*, a concept in real analysis that describes the oscillatory behavior of functions. This metric was also inspired by the w_1 smoothness metric described in [59], though ALTV is computed in the latent space and gives equal weight to each student. ALTV is formulated as

$$\text{ALTV} = \frac{1}{N} \sum_{i=1}^{N} \left(\frac{1}{k(T_i - 1)} \sum_{t=1}^{T_i - 1} \| z_{i,t+1} - z_{i,t} \|_1 \right),$$

where $z_{i,t} \in \mathbb{R}^k$ is the latent proficiency vector for student $i \in \{1, \cdots, N\}$ at time point t. Under the 1PL MIRT measurement function, each latent dimension enters the logit with a binary coefficient. Consequently, holding all else fixed, a one unit perturbation to $z_{i,t}$ in any latent dimension has the same effect on the logit. This means latent dimensions share units and the use of the L^1 norm over the differences $(z_{i,t+1} - z_{i,t})$ is justified.

3.3.2 Simulation Study

In the simulation study, we evaluated UNVaMP-MIRT under five levels of Gaussian measurement noise, perturbing each student response using

$$P\left[Y_{i,j} = 1 \mid \theta_i, a_j, d_j\right] = \frac{1}{1 + \exp\{-(a_j^\top \theta_i + d_j + \epsilon)\}},$$

where $\epsilon \sim \mathcal{N}(0, \nu)$ and $\nu \in \{0.0, 0.25, 0.5, 0.75, 1.0\}$. For each noise level, 5 replications were conducted (25 total runs). The skill-skill covariance matrix was fixed across runs, with student proficiencies, item difficulties, and responses re-sampled within each run. UNVaMP-MIRT and baseline MIRT models were fit separately within each run, with MIRT estimates obtained via maximum a posteriori (MAP) using a standard normal prior. MAP was chosen over maximum likelihood estimation (MLE) or weighted maximum likelihood estimation (WLE) for numerical stability and reliable convergence. Both models were fit with ground-truth item parameters a_j and d_j fixed, aligning latent scales such that student latent variables were the only estimated quantities. We examined two primary behaviors of UNVaMP-MIRT: (1) latent variable recovery accuracy, and (2) the behavior of uncertainty estimates as a function of the number of observations. Each replication comprised 10,000 students with 250 responses per student (2.5M observations per run). Except where otherwise noted, all simulation analyses use UNVaMP-MIRT with $\beta = 10^{-2}$.

4. RESULTS

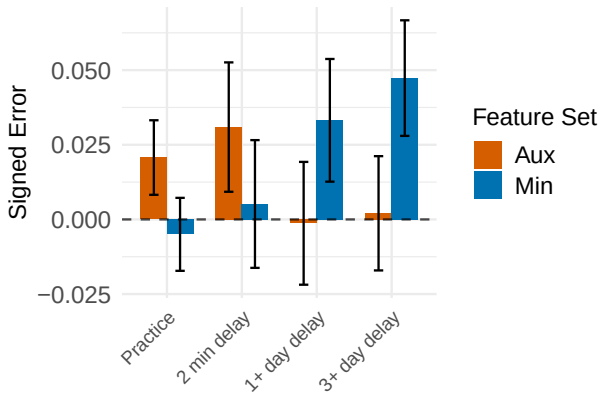

Figure 2: UNVaMP-MIRT signed error (mean$(\hat{p}-y)$) on the Cloze dataset with and without auxiliary inputs, under $\beta = 10^{-3}$. With auxiliary features included, UNVaMP-MIRT demonstrates reduced error in delayed post-tests. Error bars represent 95% confidence intervals. Standard errors were computed as the SD of prediction residuals divided by the square root of the subset sample size (practice session, 2 minute delay, 1+ day delay, or 3+ day delay).

4.1 Model Benchmarking

UNVaMP-MLP achieved the strongest overall performance during model benchmarking, outperforming or matching all other models on three of four datasets in both AUC and accuracy, with LKT performing best on the Cloze dataset (Table 2). UNVaMP-MIRT performed competitively, with only modest losses in predictive performance relative to UNVaMP-MLP, indicating that the cost of an interpretable response model is small in practice. Specifically, UNVaMP-MIRT outperformed SAINT on ASSISTments, EdNet, and Cloze, and performed slightly worse on the Amplify dataset. Compared to LKT, UNVaMP-MIRT performed comparably on ASSISTments and EdNet, and better on the Amplify dataset, though worse on Cloze. Both UNVaMP variants showed strong performance across datasets, despite varying dataset sizes, item and skill counts, and other structural attributes, indicating robustness to dataset-specific characteristics. By contrast, SAINT's performance appeared to be highly sensitive to dataset size, consistent with its transformer-based architecture. Differences between our baseline model results and those reported in the original works are primarily attributable to our data preprocessing and subsampling choices.

LKT's strong performance on Cloze is unsurprising, given that the data were collected under constrained, experimental conditions, with relatively few students and observations, limiting the performance of higher-capacity DLKT methods. LKT also benefited from hand-designed, research-based features, which can outperform deep learning methods in low- and medium-data settings [15]. Furthermore, Table 2 shows that the impact of auxiliary inputs on UNVaMP's aggregate predictive performance was minimal, with their inclusion producing negligible performance differences for UNVaMP-MLP and small, mixed effects for UNVaMP-MIRT.

Although auxiliary features had a limited impact on aggregate predictive performance for UNVaMP, results for the Cloze dataset—with its spacing, repetition, and retention interval manipulations—indicate that these features meaningfully influenced model behavior. Stratifying UNVaMP-MIRT performance by post-test session interval revealed that longer retention intervals were associated with smaller signed prediction errors for the auxiliary configuration (Fig. 2). This suggests that auxiliary features (e.g., elapsed time) can improve sensitivity to meaningful underlying structure, despite modest losses in aggregate accuracy. We suspect this sensitivity would improve, and perhaps come at reduced predictive cost (if any), given a larger dataset.

To examine the effect of β on predictive performance, we evaluated UNVaMP-MIRT (aux) under the conditions $\beta \in \{0, 10^{-3}, 10^{-2}, 10^{-1}\}$, revealing a clear pattern (Table 3). Increasing β from 0 to 10^{-3} produced no meaningful change in prediction accuracy, whereas the change from 10^{-3} to 10^{-2} led to a small but consistent decrease across datasets. A further increase to 10^{-1} resulted in a substantial accuracy drop in most cases. These results indicate that small values of β have little practical impact on predictive performance. Across all datasets, ALTV decreased monotonically with increasing β, confirming that β provides control over the smoothness of latent trajectories. With the exception of Cloze, the increase in β from 0 to 10^{-3} resulted in the largest decrease in ALTV by far. Subsequent β increases showed diminishing returns, along with increased performance penalties. The smoothing effects of β are further examined qualitatively in the simulation study results below.

4.2 Simulation Study

In the simulation study, we evaluated UNVaMP-MIRT's ability to recover student latent variables relative to a baseline MIRT model. Fig. 3(a) shows that, across all noise conditions, UNVaMP-MIRT performed comparably to the MIRT baseline once it had observed the full response sequence. Given the large number of responses per student, MAP shrinkage in the MIRT baseline model is unlikely to have materially affected accuracy. These results do not indicate that UNVaMP-MIRT will outperform MIRT under idealized conditions, but rather that it is capable of recovering latent variables with comparable accuracy given sufficient data. UNVaMP-MIRT's competitive recovery accuracy in this experiment may partly reflect its ability to implicitly exploit the cross-skill correlations that were built into the simulation process, whereas the baseline MIRT models were fit under a simple per-skill standard normal prior.

Fig. 3(b) shows that UNVaMP-MIRT's uncertainty estimates decreased alongside recovery RMSE across noise conditions, indicating that model uncertainty tracked recovery accuracy. Uncertainty declined more rapidly than RMSE early in the sequence, suggesting some possible early overconfidence, but both quantities exhibited a shared monotonic decrease. Fig. 4 illustrates the effect of β on latent variable estimation, with larger values producing less volatile estimation behavior. We emphasize that this simulation study considered static ground-truth latent knowledge states; further analysis is needed to evaluate model behavior under dynamically evolving states.

Table 2: Model performance across four real-world datasets. Best values per dataset, per metric are in bold.

	ASSISTments		**EdNet**		**Cloze**		**Amplify**

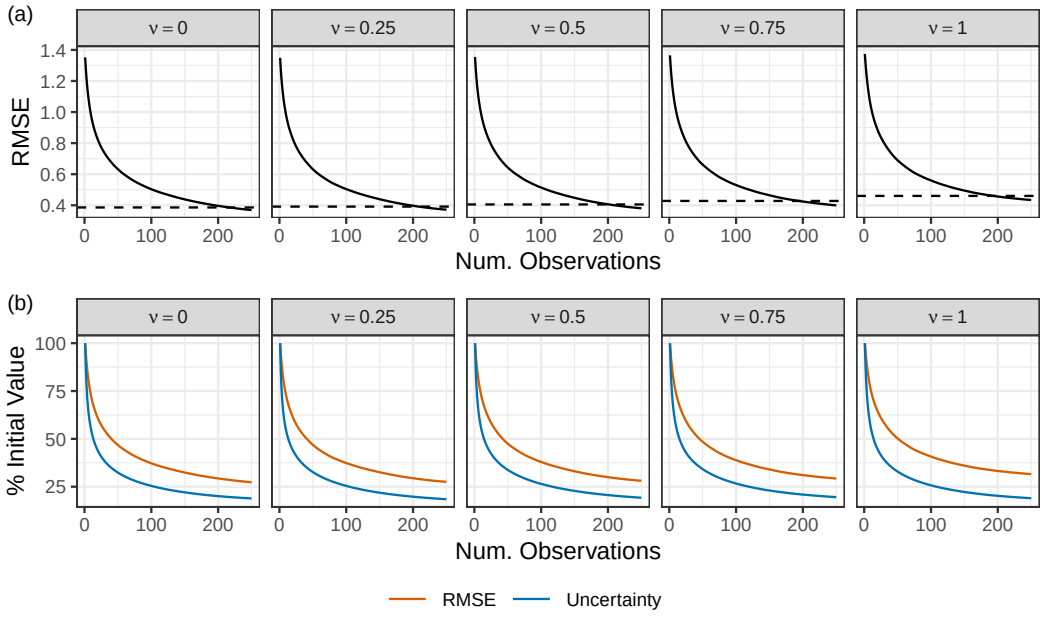

Figure 3: Relationship between the fit metrics of interest and the number of observations (student-item interactions). Panel **(a)** shows RMSE vs. observation count, averaged across replications. Cross-replication SD is omitted from the figure due to small magnitude (averaging below 0.01 for all noise conditions). The dashed line indicates baseline MIRT final RMSE, computed after observing all data. Panel **(b)** shows the percent of the initial value (RMSE and uncertainty) vs. observation count, averaged across replications. Again, cross-replication SD is omitted from the figure due to small magnitudes (averaging below 1% for RMSE and below 3% for uncertainty across all noise conditions).

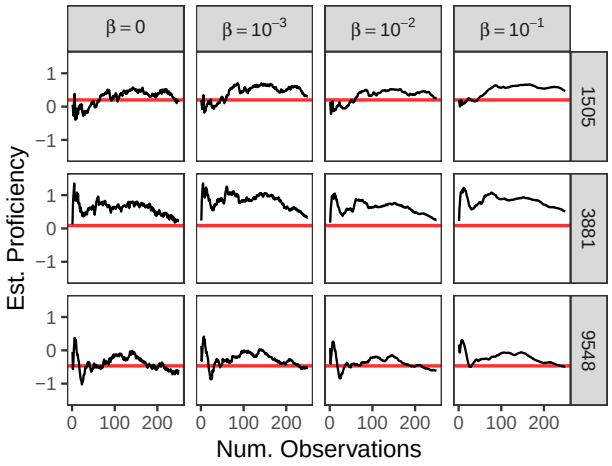

Figure 4: Effect of β on latent proficiency estimation. Columns correspond to $\beta \in \{0, 10^{-3}, 10^{-2}, 10^{-1}\}$; rows correspond to individual simulated students. The black line shows the UNVaMP-MIRT estimate for one latent skill plotted against the cumulative number of responses across all skills. The red horizontal line denotes the true value of the selected skill.

5. DISCUSSION

In total, our findings show that UNVaMP offers practical mechanisms for regularizing latent dynamics and modeling latent structure within student-item interaction data, all while maintaining competitive predictive performance. Below, we clarify the scope and limitations of the current work and place these results in a broader context.

5.1 Limitations and Future Work

Although ALTV quantifies the effect of β on latent trajectory smoothness, connecting such metrics to practical criteria for β selection is not straightforward. For instance, student knowledge estimates are expected to exhibit high early volatility, due to both estimation noise and genuinely rapid early learning, followed by more moderated trajectories. It remains unclear how to weigh smoothness against predictive accuracy, or whether such measures would have an intuitive interpretation. These issues arise because, although a hybrid UNVaMP configuration offers interpretable snapshots of estimated student knowledge, the underlying dynamics are still the product of a deep learning model and are not governed by interpretable updating rules.

Likewise, while UNVaMP provides quantitative uncertainty estimates, those estimates are not calibrated according to any interpretable statistical framework and should not be used to provide coverage guarantees; rather, they are best used to identify changes in relative confidence within the model as evidence accumulates. Because our current study examined the relationship between UNVaMP's latent uncertainty estimates and recovery accuracy only under simulated conditions, the relationship between uncertainty and external signals (e.g., predictive accuracy) should be investigated in a real-world setting; however, such investigations would need to account for the sparsity, noise, and heterogeneity of real-world interaction data.

UNVaMP can utilize arbitrary engineered features as auxiliary inputs, such as those used in LKT models. Future work could examine the impact of incorporating these features on both predictive performance and interpretability. In addition, subsequent studies could investigate UNVaMP's ability to implicitly recover experimentally demonstrated learning phenomena from data in which such structure is known to be present. While experimentally generated datasets such as Cloze are valuable for this purpose, their limited size constrains the direct application of DLKT methods. Accordingly, future work could include large experimentally informed simulation studies to examine how auxiliary inputs influence UNVaMP's sensitivity to known learning phenomena.

5.2 Conclusions

In this paper, we introduced UNVaMP, a neural network knowledge tracing architecture that estimates latent distributions over student knowledge as it evolves over time. We found that a pure neural configuration (UNVaMP-MLP) achieved the strongest predictive performance among compared models on three out of four datasets, while a hybrid configuration (UNVaMP-MIRT) lagged only slightly behind, highlighting the relatively small penalty incurred for improving interpretability. In addition, UNVaMP-MIRT with auxiliary inputs exhibited sensitivity to underlying temporal structure in the experimental Cloze dataset. Under simulated conditions, the UNVaMP-MIRT configuration further exhibited robust latent variable recovery and internally consistent uncertainty behavior. Taken together, these results indicate that UNVaMP, particularly in its hybrid configuration, is a practical solution for applications that require not only strong predictive performance, but also regularized latent knowledge trajectories, interpretable knowledge state estimates, internally consistent uncertainty quantification, and flexible input modeling.
